9. Immediately after birth, many women will naturally start to sit back. If the woman sits before passage of the newborn to her arms, she may sit on the cord or newborn. To prevent this problem, the midwife instructs the woman and others assisting with the birth on what to expect both prior to and during the birth process.

Hand Maneuvers for Birth of the Infant When the Woman Is in a Deep Squatting or Supported Squat Position

Upright and squatting positions during the second stage of labor and/or birth are associated with a shorter duration of the second stage of labor, fewer abnormal fetal heart rate patterns, and reduced severity of maternal pain. These positions are also associated with an increase in the incidence of second-degree perineal lacerations and more frequent estimated blood loss of more than 500 mL. A squatting position enlarges pelvic diameters and gravity may aid fetal descent. Depending on placement of the woman's legs, this position can tighten the transverse tension on the perineum.[10-12]

To facilitate visibility, access, and control when the woman is in a squatting position, the midwife sits on a low stool or the floor in front of the woman. In a deep squat, the woman's legs are bent and abducted, with weight bearing distributed between her legs and feet. This position brings the perineum close to the surface she is squatting on, so the infant emerges just inches above the surface. Moreover, the curve of Carus is such that the natural arc of the infant's path is into the woman's arms as an extension of the arc.

In the supported squatting position, the woman's buttocks can be partially supported by the edge of a broken birthing bed, a birthing chair, or a stool. The woman may use a squatting bar or handles on the stool, which then distributes her weight bearing between her hands, buttocks, legs, and feet. The woman may also be supported in a semi-squat position by another person. This person may stand against a wall for back support, holding the woman under her arms and across her chest. Both people bend their legs and squat gently, while the woman bears down with support from behind. It is helpful to place a pillow on the floor between the pair's legs so that there is a place to slide down onto and sit after the birth. There is usually ample space between the perineum and floor for assisting with birth in a supported squat. The perineum may be less taut when the woman is in a supported squatting position compared to the deep squatting position.

The following hand maneuvers are performed to support the woman giving birth in a

squatting position:

1. As the vertex appears at the vaginal introitus, flexion of the crowning vertex should be maintained with the palmar side of the fingers and hand. Perineal support can be provided in the same manner described previously for other positions, but is done by feel—not by sight—in this position.
2. It is important to watch the introitus while the head extends and is born, paying attention to the labial borders. When the vertex emerges with the woman in a squatting position, the pressure exerted on the introitus is distributed equally between the labia and the perineum. Lacerations along the labial borders are more common but tend to be shallow if extension of the head is controlled.
3. Using the maneuvers described previously, the newborn may be delivered to the maternal abdomen, where the woman can easily grasp and hold her baby if she is supported.
4. The hand maneuvers involved in checking for a nuchal cord, wiping the infant's head, watching for restitution and external rotation, and delivering the anterior and posterior shoulders and body are the same as described previously.

Umbilical Cord-Clamping at Birth

DEBRA A. ERICKSON-OWENS AND JUDITH S. MERCER

Introduction

A delay in clamping the umbilical cord results in a placental transfusion that supplies the newborn with a major source of iron-rich red blood cells, stem cells, and plasma. Placental transfusion continues for several minutes after birth if the umbilical cord is not clamped, and results in approximately 30% more blood volume and 50% more iron-rich blood cells being delivered to the newborn compared to immediate clamping of the umbilical cord.[1] Recent randomized controlled trials have demonstrated both short- and long-term benefits of delayed cord-clamping (DCC) for term and preterm newborns, without any adverse effects.[2] The focus of this appendix is on the use of DCC for term newborns.

Overview

The World Health Organization recommends DCC for up to 3 minutes.[3] The American College of Nurse-Midwives (ACNM) position statement (2014) on delayed umbilical cord-clamping recommends waiting at least 5 minutes before clamping this cord.[4] Immediate cord-clamping in term infants is usually defined as clamping and cutting the umbilical cord within 30 seconds after birth.[5] The definition of DCC varies but is often defined as clamping that occurs 1 to 3 minutes after birth.[3-7] A delay of 5 minutes or more is encouraged when the infant is held skin-to-skin (above the level of the placenta).[5,8] Benefits for preterm infants include improved hemodynamic stability resulting in less intraventricular hemorrhage, reduced rates of neonatal transfusion in the neonatal intensive care unit (NICU), higher blood volume and blood pressure, and less bronchopulmonary dysplasia.[2,9,10] Benefits for term infants include higher birth weights and increased early hematocrit levels, better iron stores in infancy along with less anemia, and more myelin in early-developing areas in the brain.[8]

Key Points

- Delay of cord-clamping substantively increases iron stores in early infancy. Inadequate iron stores in infancy may have an irreversible impact on the developing brain despite oral iron supplementation.
- Gravity influences the amount of placental transfusion the newborn receives. Placing the newborn skin-to-skin with the mother immediately after birth requires a longer delay of cord-clamping.
- Uterotonics can be safely administered before clamping the umbilical cord.
- Cord milking is a safe alternative to DCC when it is necessary to cut the cord prematurely.
- The concern that DCC can cause hyperbilirubinemia or symptomatic polycythemia is unsupported by the available research.
- In complex clinical situations, the management of DCC is inconsistent between types of birth settings.
- A change in cord-clamping practice requires collaboration between all types of providers who attend births.

Management Steps

Briefly review the benefits of placental transfusion with the laboring woman and her support persons. Explain that DCC at the time of birth is standard practice, unless the woman requests otherwise.

There are several issues to consider for the management of cord-clamping including: timing, position of the newborn, use of uterotonics, cord milking, the influence of the birth setting, and complex clinical situations

Timing

- Gravity affects the amount of placental transfusion that the newborn receives. Holding the newborn below the level of the placenta accelerates the transfusion, while holding the newborn above the level of the placental slows the transfusion. Holding the baby skin-to-skin requires a little longer delay.[4,5,11-13]
- Once the transfusion is complete, the umbilical cord will become pale, white, and flat and look obviously emptied, at which point the umbilical cord can be clamped and cut.[4,13] "Wait for white" is a mnemonic that is used to signal when the transfusion is complete.
- Cessation of palpable pulsations of umbilical cord vessels means only that the umbilical arteries have constricted; it does not indicate that it is time to clamp the cord. There is still more blood left behind in the placenta that will be transferred to the newborn during the third-stage uterine contractions.[12]

Position

- Place the newborn and woman skin-to-skin. Dry and cover the newborn with a warm blanket, and leave the umbilical cord intact for at least 5 minutes or until the placenta is ready to emerge. Only newborns with good tone and respiratory effort should go immediately onto the maternal abdomen.[5,12]
- For any woman who does not want skin-to-skin placement of her newborn, place the newborn on a clean pad, between the woman's legs, and wait for the transfusion to complete.[12]

Use of Uterotonics

- Uterotonics can be safely administered before clamping the umbilical cord.[7,14]
- The use of uterotonics may speed the rate of placental transfusion by increasing the strength and frequency of uterine contractions. A widely held misconception is that the newborn will be over-transfused; however, the evidence is clear that over-transfusion does not occur.[13]

Umbilical Cord Milking

When it is necessary to transfer the newborn to a warmer for resuscitation, an alternative procedure is to milk the umbilical cord.[5,12,13] While milking the cord does not provide as much blood to the newborn as DCC, it does provide the newborn with some additional blood and red cell volume.[4,5]

To milk (or strip) the cord, a portion of the cord nearest the introitus is grasped between the thumb and the forefinger and the cord is then compressed (milked) down the length of cord toward the newborn's umbilicus 3 to 5 times. Following a vaginal birth, start at the introitus; at time of cesarean birth, start near the insertion site on the placenta. Take about 2 seconds to move over the length of the cord; wait about 2 seconds for cord to refill after milking, and then milk again.[13,15]

Complex Clinical Situations

Tight Nuchal Cord

Approximately one-third of all newborns are born with a nuchal cord. Usually this is a nonemergent event. A tight nuchal cord is less common but can be associated with hypovolemia in the newborn. Keeping the cord intact is strongly encouraged and can be supported by performing the somersault maneuver (**Figure 28A-2**).[16] This can be followed by transitioning (or resuscitation) with an intact cord.[17]

Shoulder Dystocia

Hypovolemia frequently accompanies a shoulder dystocia. After a birth that is complicated by a shoulder dystocia, assess the newborn and use techniques such as DCC or cord milking to restore blood volume before clamping. If the shoulder dystocia is accompanied by a tight nuchal cord, avoid clamping before birth of the newborn's shoulders.[18]

Slow-to-Start Newborn Requiring Neonatal Resuscitation

If the newborn has poor tone or is "slow to start," a plan of action is needed to support a safe neonatal transition.[13,18] Providers in out-of-hospital settings usually resuscitate the newborn at the perineum while maintaining an intact cord.[19] The hospital setting is challenging in this respect, and the provider may or may not be able to resuscitate with an intact cord (except if part of a research study).

Resuscitation with an Intact Cord (Delayed Cord-Clamping)

The newborn can be placed on a clean pad at the perineum or held below the level of the placenta to accelerate placental transfusion.[5] According to the Neonatal Resuscitation Program (NRP) guidelines, breathing, heart rate, and tone need to be assessed. Heart rate can be assessed by lightly feeling the stump of the cord. The heart rate is often normal even when the newborn is not initially breathing. Resuscitation, as recommended by NRP, can then proceed. The midwife should check the heart rate again; if it has not improved, all the usual resuscitation maneuvers can be instituted at the perineum without detaching the newborn. Once the newborn is breathing and tone is regained, the newborn can be placed skin-to-skin with the woman. This method of resuscitation has been practiced safely for many years in out-of-hospital settings.

Resuscitation with Cord Milking

When DCC is not feasible, and the heart rate is low, the cord can be milked 3 to 5 times toward the newborn to accelerate transfer of blood volume before clamping.[5,13] The newborn can then be moved to the newborn warmer and the usual NRP resuscitation maneuvers can be instituted.

Umbilical Cord Blood Gas Sampling

Within the hospital setting, a cord blood gas sample may be required or be a component of a standard protocol. A provider usually double-clamps (and cuts) the cord immediately after birth to collect a section of umbilical cord that can be used to obtain blood samples from the umbilical artery and umbilical vein. However, Andersson et al. demonstrated a technique that supports cord gas sampling while maintaining an intact cord.[20] With this procedure, an assistant holds the newborn immediately after birth. The midwife then uses both hands to collect the umbilical cord blood gas samples. Using a tuberculin syringe(s) with a very small-

gauge needle (25 or 27 gauge), the sample is collected from an umbilical artery first and then the umbilical vein. A small 2 × 2 gauze pad is placed over the insertion site and very gentle pressure applied to stop the oozing. The DCC is maintained and, if appropriate, the newborn is placed skin-to-skin with the woman.

APPENDIX

28C

Genital Tract Injury: Immediate Postpartum Inspection of the Vulva, Perineum, Vagina, and Cervix

BARBARA J. REALE

The editors acknowledge Lisa Kane Low, who contributed to this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

Inspection of the vulva, perineum, vagina, and cervix for the presence of lacerations or hematomas takes place immediately after the birth. During this inspection, the midwife identifies:

- The presence of any arterial bleeding that needs immediate repair
- The location and type of lacerations
- Whether the lacerations require repair[1,2]
- The presence or absence of a hematoma

Key Points

Pain Relief

Inspection of the vagina and cervix can be uncomfortable or painful. The first step is to determine whether a woman is bleeding heavily from a laceration. If so, hemostasis must be achieved prior to or simultaneously with analgesic considerations. Hemostasis may be achieved with manual pressure, application of hemostats, or suture.

Once hemostasis is achieved, the midwife must determine whether the woman needs an

analgesic for the inspection. This decision will depend both on how extensive the inspection is likely to be and what the woman's pain threshold is. If an extensive inspection or repair is likely, a woman may need an intravenous dose of an opiate such as fentanyl or morphine. If she has an epidural, the anesthesiologist should be made aware that an inspection is needed so that the epidural can be used to provide the necessary pain relief. If the woman has a patient-controlled epidural analgesia pump, she should be asked to press the button for another dose. A pudendal or local injection of anesthetic may be given as needed.

Adequate Lighting

Ensure that an adequate lighting source is available. Inadequate lighting can result in misidentification of a laceration or a prolonged inspection and repair. It may be necessary to move the woman to a different place or different room to ensure adequate visualization.

Positions for the Woman and the Provider

Position the woman in a manner that will maximize her comfort and also allow the midwife to conduct an adequate examination. For most inspections, having the woman assume a modified lithotomy position by reclining and flexing her knees and placing her feet on the bed or other surface is sufficient. However, if an upper vaginal vault or cervical laceration is suspected, positioning the woman in foot rests or stirrups may be preferable if available.

Visualization

The midwife will need to insert three or four fingers into the vagina to provide space to allow visualization of the cervix and possibly the apex of a vaginal tear. Alternatively, a Sims retractor may be inserted with pressure against the anterior vaginal wall for better visualization of the vagina. Actions to be taken include:

- Assessing whether the laceration is hemostatic or bleeding
- Identifying the exact location of the laceration so that it can be described in the woman's chart and to other providers who may be involved in the woman's postpartum care
- Determining which type of laceration is present (**Table 28-10**) and whether the laceration requires repair

Equipment

- Sterile gloves
- Sterile gauze pads (or lap sponge pads detectable by X ray)
- Tissue forceps
- Vaginal retractor (Sims)
- Two ring forceps
- Antiseptic solution

Procedure for Examination of the Vulva and Perineum

1. Inspection of the vulva and the perineum is achieved by using sterile, gloved fingers to gently separate the labia. A sterile cloth or gauze may be used to gently clean away blood or clots that obscure a laceration.
2. The periurethral, periclitoral, labial, fourchette, perineal, and rectal areas are completely visualized.
3. The edges of irregular lacerations may be visually approximated best if a tissue forceps is used to carry one side of the laceration to the other. This helps the midwife begin a plan for repair of the laceration.
4. If a third- or fourth-degree laceration is suspected, don an additional glove and insert the index finger into the rectum to assess the integrity of the rectal sphincter. With palmar side up, gently lift upward, to expose the full extent of the laceration. Remove this glove and discard it after the rectal examination.

Procedure for Thorough Examination of the Vaginal Vault

For the purpose of this procedure, the vaginal vault is divided into four sections: posterior, anterior, and two lateral walls. Each section is visualized to identify lacerations in the vaginal mucosa. A systematic approach to this examination ensures that all areas are quickly, yet thoroughly inspected. Gauze sponges should be counted prior to use.

1. A 4 × 4 gauze sponge folded in fourths and clamped with a long-length ring forceps can be used to clean away blood. A second ring forceps can be used to gently lift a prolapsed cervix, or a Sims retractor used to elevate the anterior wall, allowing an unobstructed view of the lateral, posterior, and anterior fornices of the vaginal vault.
2. To examine each section of vaginal wall, insert the full length of several fingers of one sterile, gloved hand palmar side down and exert pressure away from the area being examined. Once one area has been inspected, release the pressure and reposition the vaginal hand in the new area to be inspected before force is applied again.
3. Insert the ring forceps with the gauze sponge on it by sliding it down the top of the vaginal fingers. This maneuver minimizes the amount of gauze touching the vaginal walls, as the gauze is abrasive to these tissues. The gauze serves as a sponge to blot blood and other fluids from the exposed area, thus, facilitating visualization. If the gauze sponge becomes saturated, remove the ring forceps, dispose of the saturated gauze sponge, clamp on a clean one, and reinsert the ring forceps. During this procedure, the midwife should be careful to monitor use of gauze sponges so none is inadvertently left in the vagina. Dedicating an area on a delivery table or drape for saturated sponges to be counted is helpful.

Procedure for Inspection of the Cervix

An assistant, if one is available, will make this procedure easier and more efficient.

1. Insert three or four sterile, gloved fingers of the nondominant hand palmar side down along the posterior vaginal wall to the area just in front of the cervix. This hand is used to exert pressure to retract the posterior vaginal wall and facilitate visualization of the cervix.
2. Once the cervix is in view, using the dominant hand, grasp the anterior lip of the cervix with one of the ring forceps. The first forceps is used to help bring the anterior part of the cervix into view. The second ring forceps is used to grasp the posterior part of the cervix (**Figure 28C-1**).
3. Hold the handles of *both* ring forceps in the dominant hand. Pull on the forceps gently, if necessary, to bring the cervix more into view. Move the handles of the forceps toward one side of the perineum, thereby slightly pulling the cervix so the lateral apex of the cervix can be visualized.
4. Visually inspect the area of the cervix between the two ring forceps on one side.
5. If necessary, confirm the visual inspection by using the index finger of the vaginal hand to feel the edge of the cervix.
6. Repeat the procedure, moving the handles of the forceps toward the other side of the perineum to visualize and inspect the other lateral side of the cervix.
7. If the cervix is very patulous, all of the cervix may be difficult to visualize adequately between the ring forceps placed on the anterior and posterior lips of the cervix. In such a case, the entire circumference of the cervix can be visualized by placing one ring forceps on the anterior lip of the cervix and the second forceps next to it. Release the first forceps and place it on the other side of the second. Continue to leap-frog or "walk" the ring forceps around the cervix. This technique can also be used when the posterior lip of the cervix cannot be located easily.
8. If there are no cervical lacerations, remove the ring forceps and the vaginal hand.
9. If the cervix is bleeding from a cervical laceration, use the forceps to exert direct pressure on the laceration to decrease or stop the bleeding, prior to repair. This method can help to significantly reduce the amount of blood lost.

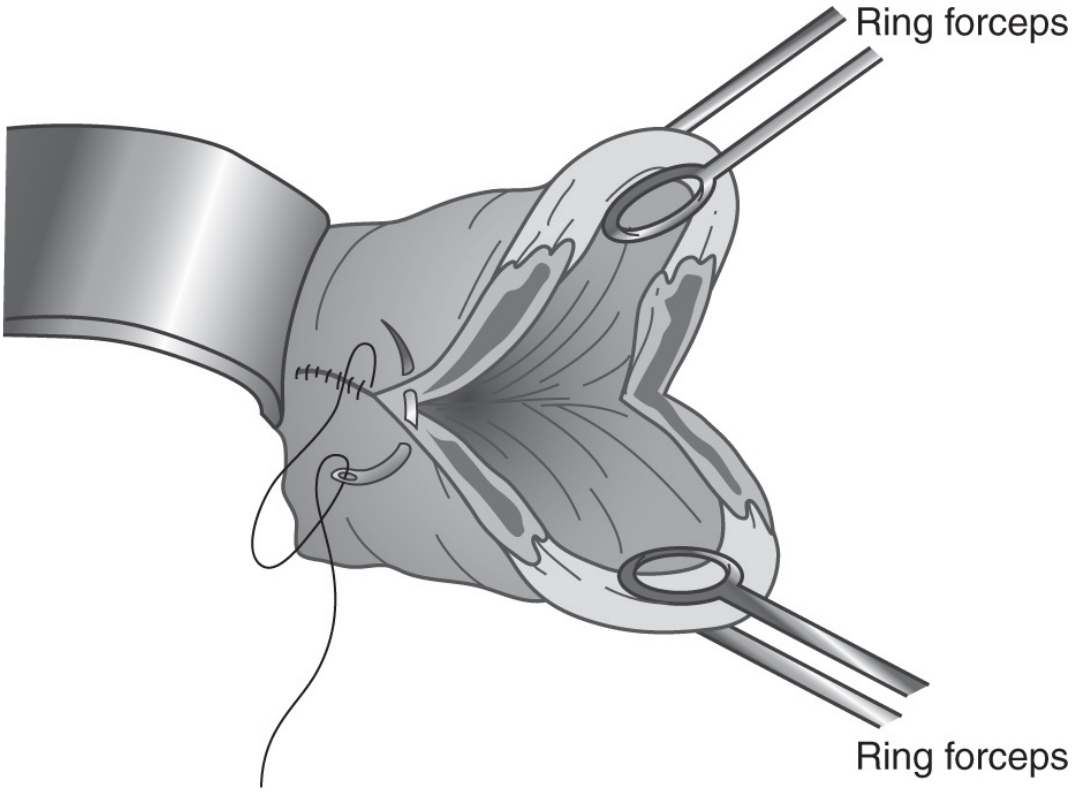

Figure 28C-1 Visualization of the cervix.

Hematomas

During pregnancy, the vagina and vulva have rich and full vascular beds that are at risk for experiencing trauma during childbirth. When one of these vessels is torn or damaged, a hematoma can occur and enlarge very quickly.[3] Most hematomas develop from vessels torn during a vaginal or perineal laceration, but vessels can also be injured withoutobvious laceration. Hematomas develop rapidly and are extremely painful for women who do not have regional anesthesia. A classic presentation is pain that is unrelieved or worsens despite administration of pain medication. The most common symptom in women who have epidural anesthesia is rectal pressure or rectal pain. Hematomas are reviewed in more detail in the *Third Stage of Labor* and *Postpartum Complications* chapters.

Because hematomas often occur secondary to a tear in an artery, significant blood can be lost and the woman can develop signs of shock. The most common locations where hematomas develop are the vulva, the vagina, and the retroperitoneum.[4]

Vulvar hematomas develop secondary to damage to one of the branches of the pudendal artery. Because the Colles' fascia and urogenital diaphragm or anal fascia prevent their expansion, these hematomas grow superficially toward the skin and loose subcutaneous tissue. They present as swellings in the labia majora.

Vaginal hematomas are the result of injury to the uterine artery. These vessels are not surrounded by fascia, and bleeding into the paravaginal area can be extensive.

Retroperitoneal hematomas that extend between the folds of the broad ligament are rarer than the other two types. These hematomas are caused by injury to the branches of the internal

iliac artery and are more common following uterine rupture or as an extension of a paravaginal hematoma. Hemorrhage can be significant, and hemodynamic instability can develop quite quickly. Bleeding can be either arterial or venous. Women who are hemodynamically stable usually have a venous bleed; conversely, women who become hemodynamically unstable are more likely to have an arterial bleed.

Local Infiltration for Laceration Repair

BARBARA J. REALE AND TEKOA L. KING

The editors acknowledge Lisa Kane Low, who contributed to this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Local infiltration of an anesthetic solution can be placed in the perineum just prior to birth before cutting an episiotomy. In addition, it can be administered specifically in the areas or structures involved that need to be sutured after a spontaneous laceration occurs.

Anesthetic Agent for Local Injection

The medication recommended for local infiltration of tissue that requires sutures is 1% lidocaine hydrochloride (Xylocaine) 10 mg/mL. Lidocaine is available either with or without added epinephrine. Epinephrine produces vasoconstriction—an action that helps retain the drug in the tissue being sutured longer, thereby extending the period of anesthesia.

Pharmacokinetic studies have found that lidocaine is detected in maternal plasma within a minute of injection and that placental transfer occurs quite rapidly.[1] It is theorized that potential adverse effects of epinephrine on the uterine blood flow and fetus could be significant. Because of this risk, lidocaine with added epinephrine should *not* be used prior to birth. In contrast, lidocaine *with* added epinephrine is used for local infiltration after birth because less overall drug is needed and the anesthetic effects last longer.[2]

Lidocaine Toxicity

Lidocaine toxicity can cause light-headedness, dizziness, tinnitus, abnormal taste, facial tingling, circumoral numbness, and confusion. Severe toxicity results in loss of consciousness and respiratory arrest. If lidocaine without epinephrine is injected intravascularly, the first signs may be hypotension and bradycardia. If lidocaine with epinephrine is injected intravascularly, the first signs may be hypertension and tachycardia.

Toxicity is usually the result of intravenous injection, rapid absorption from a very vascular area such as mucous membranes, or overdose. Thus, a maximum dose that is safe to use is specified for lidocaine. Toxic levels of lidocaine can be administered if accidental intravascular injection occurs or if the total volume of medication injected is not monitored. Toxic levels are based on the weight of the woman, the concentration of the medication, and an identified safe range for administration.

Case reports of toxic levels of lidocaine in the fetus have been described secondary to direct injection into the fetal scalp. The risk of this unanticipated event is more likely if the fetus is in an occiput posterior (OP) position or if large amounts of lidocaine are injected more than 4 minutes prior to the birth.

Lidocaine Dose and Pharmacokinetics

- The recommended dose of lidocaine 1% *without* added epinephrine is typically 5 to 10 mL (50–100 mg). Peak plasma concentrations occur in 3 to 15 minutes, and the onset of action may take up to 3 minutes. It is important to wait until the anesthetic has taken effect. The duration of action is approximately 30 to 60 minutes.[2-4]
- The maximum dose of lidocaine 1% is based on case studies of toxicity, older animal studies' and manufacturers' recommendations.[2,3]
  - Lidocaine 1% *without* epinephrine: 30 mL (300 mg).[2,3] In Europe, the maximum recommended dose is 20 mL (200 mg), so publications may report either 200 mg or 300 mg.[2]
  - Lidocaine 1% *with added* epinephrine: 50 mL (500 mg).

Equipment for Local Infiltration

Equipment used to perform local infiltration is listed in **Table 28D-1**.

Table 28D-1	Equipment Necessary for Local Infiltration of Anesthetic Solution
Sterile gloves	
1% lidocaine (10 mg/mL)	
A 10- to 20-mL syringe	
Needles:	
18-gauge, 1½-inch needle to draw up the anesthetic from its original container	
22-gauge, 1½-inch needle for episiotomy, perineal or vaginal laceration, or a vaginal sulcus tear	
25-gauge, 1-inch needle for periurethral or clitoral lacerations	

Local Infiltration Prior to Cutting an Episiotomy

Local infiltration prior to cutting an episiotomy is done when the perineal body has been

thinned and flattened considerably by the crowning of the fetal head or pressure from the presenting fetal part. At this point, there is typically little anteroposterior tissue and only one plane that requires anesthesia. While the thin and flattened perineal body allows for easier administration of anesthetic and identification of the area where infiltration has occurred, it also presents the challenge of potentially piercing the posterior perineal wall and inserting local anesthetic uselessly into the vagina or dangerously into the fetus. To avoid this risk, the following procedure is recommended.

General Principles

1. Always inject slowly.
2. Aspirate regularly during injection to check for blood return and to avoid intravascular injection.

Procedure

1. Place two fingers of the nondominant hand 3–4 cm into the vagina between the fetal presenting part and the flattened perineal body. Bring a small amount of pressure onto the posterior perineal surface to create a space between the area where the local infiltration is going to occur and the presenting fetal part.
2. Either of two techniques for local infiltration of the perineal body may be used.
   a. Insert the needle at the center of the fourchette and direct the needle straight down the midplane toward the rectum. After aspirating, up to a maximum of 10 mL (100 mg) of lidocaine is injected as the needle is slowly withdrawn. The desired effect is to create a large, visible, and palpable perpendicular wheal approximately 2–2.5 cm wide and extending from top to bottom in the center of the perineal body (**Figure 28D-1**).
   b. Insert the needle point at the center of the fourchette and aspirate. The needle is then introduced in a manner that creates an upside-down fan shape centrally in the perineum body while the medication is being injected. This technique provides more anesthesia in a wider section of the perineum, but takes more time to perform and involves pulling the needle back up and repositioning it. The goal is to avoid multiple sticks by drawing the needle up but not removing it before re-angling and moving the needle down the perineum in the next direction (**Figure 28D-2**).
3. If the plan is to cut a mediolateral episiotomy, the direction of the needle and resultant wheal should not be placed centrally but instead directed to the side, following the intended path of the mediolateral cut that will be made.

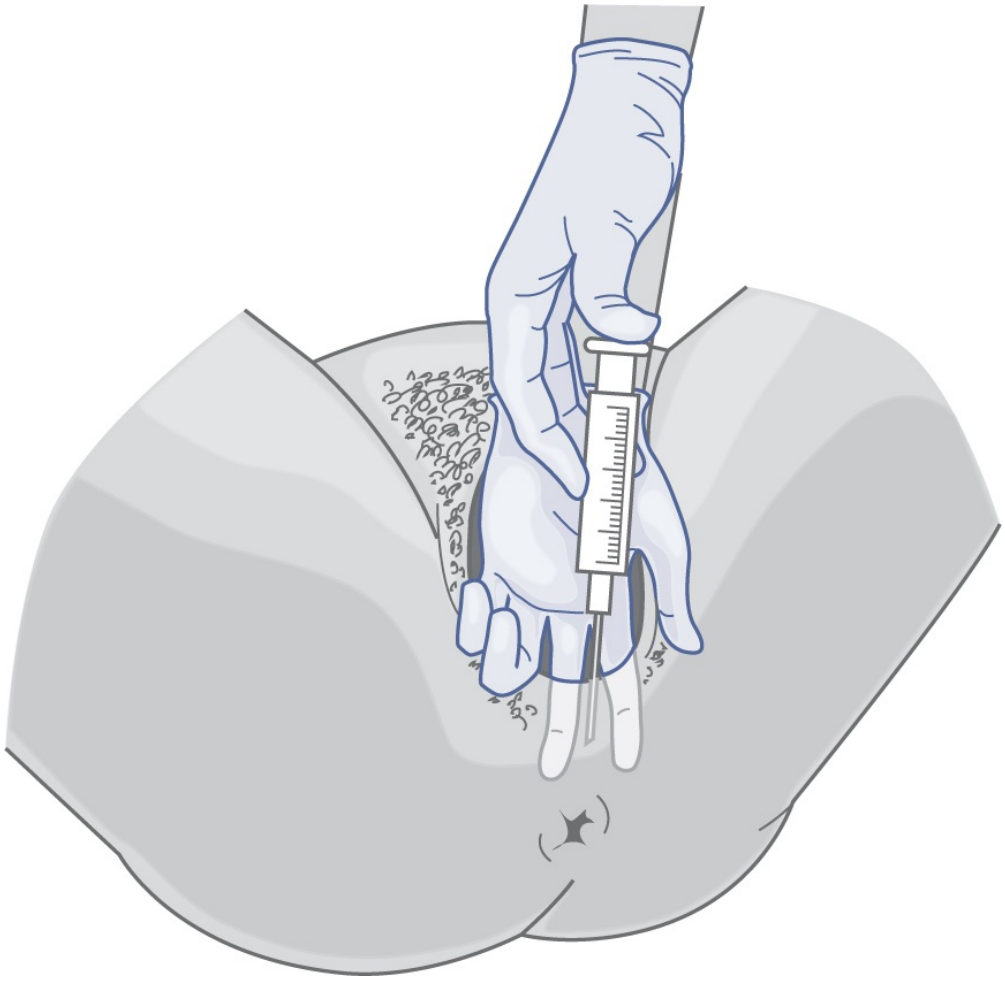

Figure 28D-1 Technique 1 for local infiltration for a midline episiotomy.

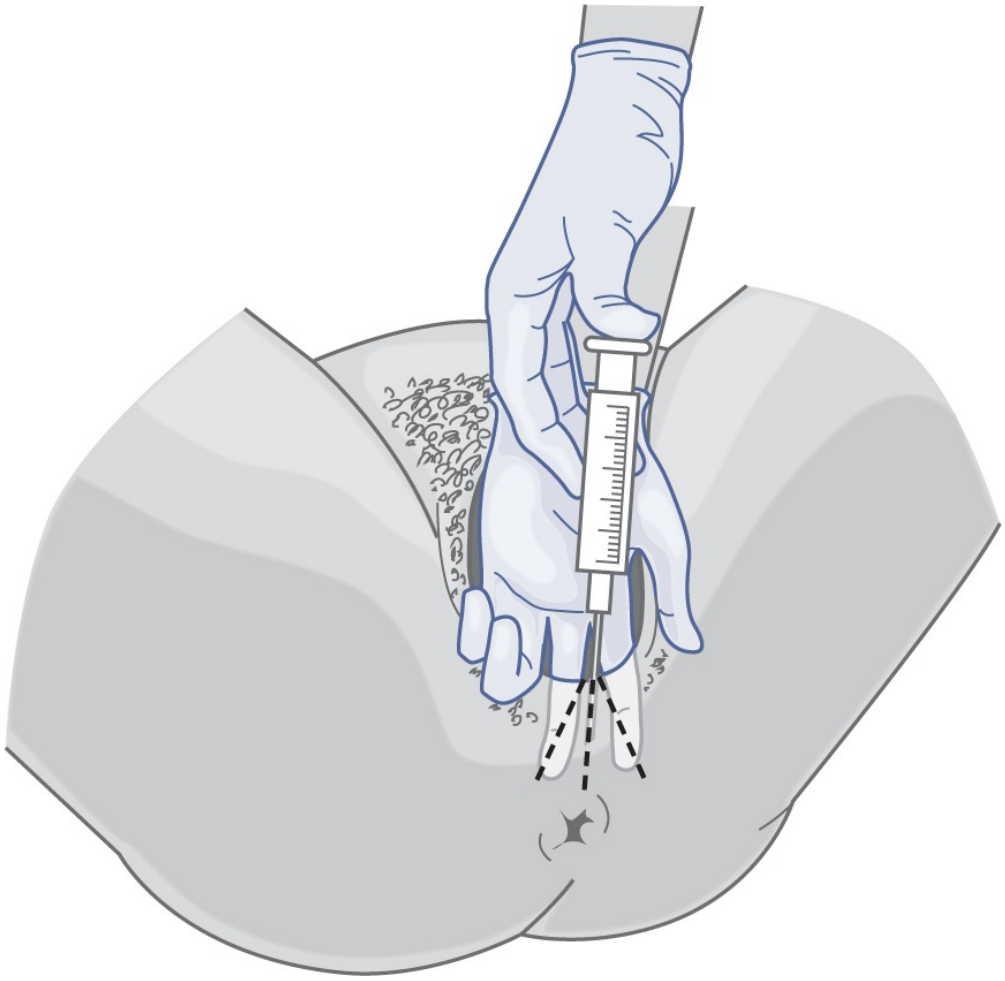

Figure 28D-2 Technique 2 for local infiltration for a midline episiotomy.

Local Infiltration for Repair After Birth

Local infiltration for repair of a laceration may be needed if pre-birth anesthesia has dissipated, a post-birth pudendal block has failed, or local infiltration is the mode of choice. The primary disadvantage of local infiltration for repair is that it distorts the tissue, thereby making tissue approximation potentially more challenging.

Procedure

1. Identify all tissue that requires anesthesia and repair.
2. Place the needle tip at the end or corner of the laceration nearest the posterior fourchette, and insert it for the length of the wound, reaching the areas where the suture needle will be either entering or exiting the tissue.
3. Aspirate to confirm that the needle is not in a vessel.
4. Inject the anesthetic as the needle is withdrawn along the line of the wound edge.
5. Discontinue injecting medication when the needle point is withdrawn to where it entered the wound, without fully withdrawing the needle.

6. Redirect the needle along the open wound in any tissue just under the wound that will require suturing.
7. Inject anesthetic as the needle is withdrawn back to the point of entrance.
8. Repeat this process until the area that needs suturing has been anesthetized.
9. Once the area requiring anesthesia is fully infiltrated, withdraw the needle. Another, noncontiguous area can then be anesthetized following the same process.

© hakkiarslan/iStock/Getty Images Plus/Getty

Pudendal nerve block is a regional anesthetic technique that anesthetizes the pudendal nerve, resulting in a reduction or elimination of pain perception in the muscles and tissue innervated by the pudendal nerve. Pudendal nerve block offers the following advantages:

- Primarily used to achieve analgesia for operative vaginal birth and/or repair of genital tract lacerations. It may also be used for late second stage pain relief with spontaneous vaginal birth, or for women who do not have adequate or satisfactory pain relief during perineal repair following instillation of local anesthesia to the perineum.
- Provides anesthesia to the vulva and anus, including the clitoris, labia majora, labia minora, and perineal body, thereby offering broader anesthesia coverage than is accomplished with local infiltration. Pudendal anesthesia does not abolish the pain of uterine contractions and cervical dilation, nor is it effective for repair of lacerations of the upper vagina and cervix, or for manual exploration of the uterine cavity.
- Does not alter the strength or frequency of uterine contractions, but may decrease the urge to push during second stage labor.
- Confers minimal risk to the parturient, fetus, or newborn when administered correctly, using the appropriate medication within the safe dosage range.

Anesthetic Agent for Pudendal Block

The anesthetic agent commonly used in pudendal nerve block is 1% (10 mg/mL) lidocaine hydrochloride (Xylocaine) without added epinephrine.[1] Lidocaine is rapidly absorbed, crosses the placenta, and is detectable in maternal venous and fetal scalp blood within 5 minutes after

injection, with peak levels attained between 10 and 20 minutes after injection.[2] A maximum block may take up to 20 minutes to achieve because the pudendal nerve is a large peripheral nerve with a smaller surface area to volume ratio, and a myelin sheath. Hence, the speed of onset of anesthetic effect is delayed, and time to maximum block takes longer to achieve than the usual 5 minutes for subcutaneous infiltration of the perineum.[3]

The duration of anesthesia depends on the success of the pudendal block and on the medication used. The average duration of action of lidocaine is 30 to 60 minutes. Safe dosing of 1% lidocaine is 3mg/kg (204 mg in a woman who is 150 lbs) to 4.5mg/kg (300 mg in a woman who is 150 lbs). The maximum recommended dose is 300 mg.[3,4]

Equipment for Pudendal Block

The equipment needed to perform a pudendal block is listed in **Table 28E-1**. The needle guide, procedure needle, and syringe used for this technique are shown in **Figure 28E-1**.[1]

Pudendal Block for Perineal Anesthesia

The pudendal nerves are the primary source of sensory innervation to the lower vagina, vulva, perineum and anus, and provide motor innervation to the perineal muscles, urethral sphincter, and external anal sphincter. Infiltration of local anesthesia around the trunk of the pudendal nerve via pudendal nerve block inhibits nerve transmission and results in pain relief to these areas. To target the pudendal nerve effectively and safely, an understanding of the location of the pudendal nerve and internal pudendal artery is essential.

Anatomic Location of Pudendal Nerve

The pudendal nerve derives from sacral roots S2-S4. It courses between the piriformis and coccygeus muscles, and exits the pelvis through the greater sciatic foramen. It then courses on the posterolateral surface of the sacrospinous ligament, medial to the internal pudendal vessels that lie on the posterior aspect of the ischial spine. Inferior to the ischial spine, the nerve travels along the lateral pelvic wall through Alcock's canal and divides into three branches (inferior rectal nerve, perineal nerve, and dorsal nerve of the clitoris).[5]

Key Principles for Achieving an Effective Pudendal Nerve Block

1. To target the pudendal nerve effectively and safely, an understanding of the location of the pudendal nerve and internal pudendal artery is essential.
2. Understand the key anatomic landmarks used to locate the optimal point of lidocaine infiltration to most effectively target the pudendal nerve.
3. Allow for a sufficient amount of time to effect adequate analgesia.

Contraindications to Pudendal Nerve Block

Contraindications to pudendal nerve block are coagulation disorders, infection in the vagina, allergy to local anesthetic, and women who are not able to cope with the procedure, or who decline pudendal nerve block.

Procedure for Administration of a Pudendal Nerve Block[1]

1. Explain the risks and benefits of pudendal nerve block and obtain consent.
2. Draw up 20 mL of 1% lidocaine into the syringe, attach the pudendal needle and clear the air from the syringe and needle. Place the needle with attached syringe into the guide.
3. Palpate the ischial spine.
   a. If the location of the ischial spine is unclear, palpate the sacrospinous ligament, and follow it laterally to its attachment point on the ischial spine. The sacrospinous ligament is a firm band of tissue that travels between the sacrococcygeal joint and the ischial spine. If the location of the sacrospinous ligament is unclear, palpate the sacrococcygeal joint (the junction between the coccyx and the sacrum), find the attached sacrospinous ligament, and walk your fingers laterally along the ligament to the ischial spine.
4. With the needle tip withdrawn into the guide, insert the guide with attached syringe into the vagina. Place the tip of the guide on the sacrospinous ligament, 10 mm medial to the ischial spine (**Figure 28E-2**).
   a. To prevent inadvertent needle sticks, make sure the needle tip is withdrawn into the guide during insertion into the vagina.
   b. To perform a right-sided block, place the right index finger on the ischial spine. Place the middle finger on the adjacent sacrospinous ligament. Holding the guide and attached syringe in the left hand, glide it along the right hand to the point between the tips of the index and middle finger.
   c. For a left-sided block, place the left index finger on the ischial spine and hold the guide and attached syringe in the right hand.
   d. The correct location of the guide directs the needle tip to the optimal point of infiltration (10 mm medial and 10-15 mm posterior to the ischial spine). The needle guide allows only 10-15 mm of needle to protrude from its end (distance varies with manufacturer of the guide).
   e. Placing the pudendal nerve block while the fetal head is deep in the pelvis can be challenging as the procedure often stimulates an urge to push. Placing it between contractions and encouraging the parturient to breathe deep between contractions

may help her to overcome the urge to bear down during the procedure.

5. Stabilize the guide.
   a. A gentle forward pressure of the index finger on the ischial spine may help to stabilize it.
6. Advance the needle through the guide and through the sacrospinous ligament to the optimal point of infiltration.
   a. Caution! When the needle is fully advanced through the guide, it will protrude from the tip of the guide. To prevent needle stick injuries, keep the needle retracted into the guide until you are ready to advance the needle through the ligament. Make sure that your fingers are not in front of the tip of the guide before advancing the needle.
7. Aspirate.
   a. This is a necessary safety measure to prevent intravascular administration. Aspiration is performed before all subsequent injections.
8. Inject 10 mL of lidocaine 1% into the first side.
   a. Alert the woman to the forthcoming injection.
9. Repeat the procedure on the contralateral side.

2. Allow sufficient time to achieve an effective block.
   a. The maximum analgesic effect may take up to 20 minutes to achieve. To test for an effective block, stroke the skin adjacent to the anus. An effective block will prevent the reflexive constriction of the anal sphincter. Repeat on the opposite side.
   b. If the block is ineffective or unilateral, 5 additional mL of 1% lidocaine may be administered. Keep track of the total dose administered and do not exceed 30mL (300 mg) of 1% lidocaine.
   c. In some cases, such as a need for an urgent birth where it may not be possible to wait up to 20 minutes to achieve maximum anesthetic effect, practitioners may first infiltrate the perineum with local anesthetic, then administer the pudendal nerve block. This will provide a more rapid anesthetic block to the perineum and help with pain relief if the effect of the pudendal nerve block is not complete before the procedure.

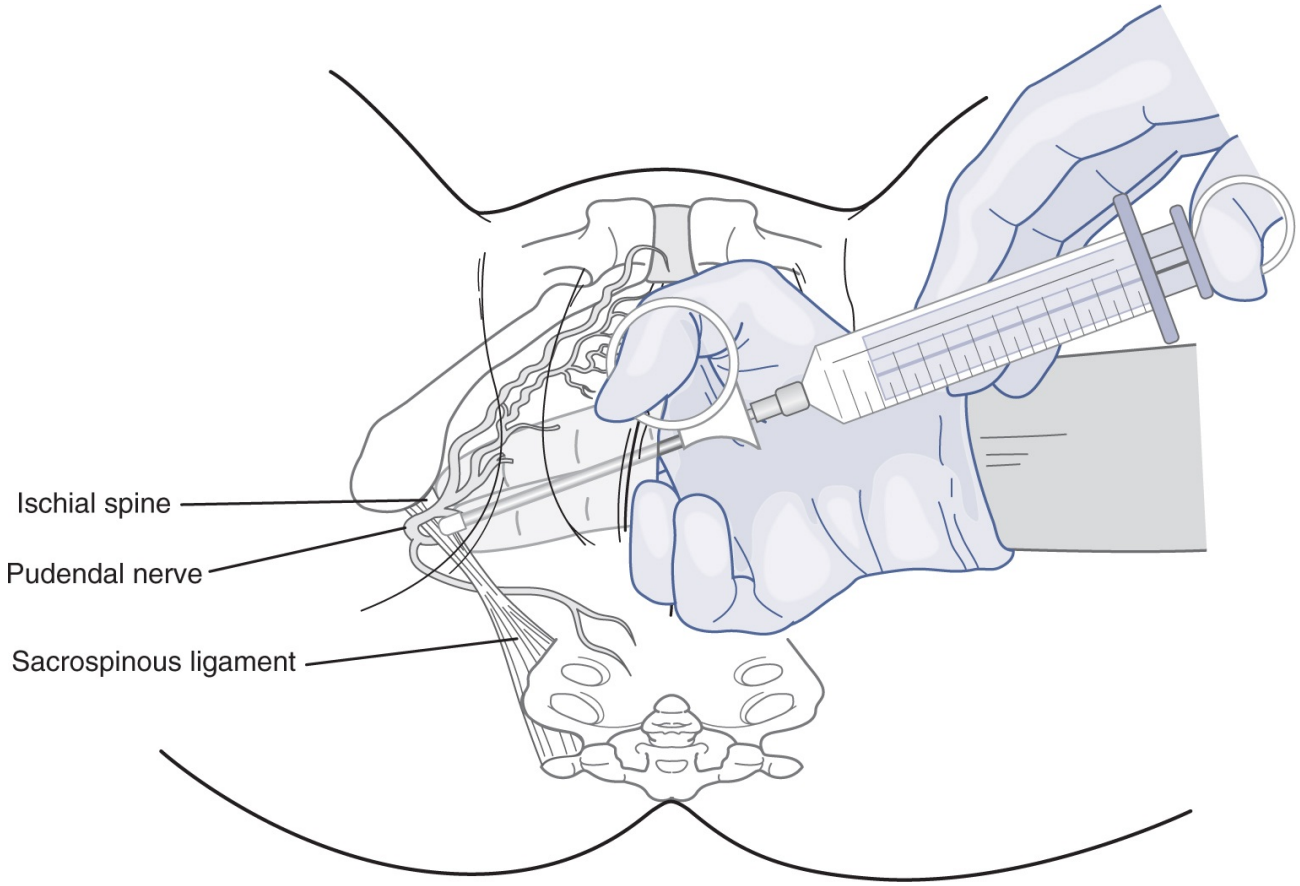

Figure 28E-2 Pudendal block procedure.

Variations of Pudendal Block Procedure: Multiple-Injection Approach

Variations of the standard procedure have been published and are summarized here.[1,4,6] The single-injection approach may minimize the risks of pudendal nerve block complications; the multiple-injection approach may decrease the chance of inadequate block. However, no studies have been conducted comparing the safety or efficacy of the single and multiple injection techniques.

Variation 1[1,6]

Follow the procedure outlined above until the point of administration of 1% lidocaine. Instead of a single injection approach:

- Inject 3 mL of 1% lidocaine into the sacrospinous ligament 10 mm medial and posterior to ischial spine.
- Advance the needle through the sacrospinous ligament and inject the remaining 7 mL.
- Aspirate before all injections.
- Repeat on other side.

Variation 2[1,4]

Follow the procedure outlined above until the point of administration of 1% lidocaine. Instead of a single injection approach:

- Inject 1 mL of 1% lidocaine into the mucosa and create a mucosal wheal just beneath the tip of the ischial spine.
- Advance the needle to the sacrospinous ligament and infiltrate 3 mL into the sacrospinous ligament.
- Advance the needle through the sacrospinous ligament and inject another 3 mL of 1% lidocaine posterior to the ligament.
- Withdraw the needle into the guide, place it just above the ischial spine, and administer an additional 3mL of 1% lidocaine.
- Aspirate before all injections.
- Repeat on other side.

Outcomes Associated with Pudendal Block

Approximately 3% to 50% of pudendal blocks will be ineffective on one or both sides.[1] Ford has suggested that poor knowledge and variable performance of pudendal nerve block may be contributing to suboptimal effectiveness.[3] Nevertheless, a pudendal block provides excellent analgesia when it is effective.

Complications of pudendal nerve block are rare but can be serious. These include hematoma with or without infection, localized infection (retropsoas and subgluteal abscess), infection at the site of injection, systemic toxicity from inadvertent intravascular administration or excessive doses of anesthetic, temporary ischial paresthesia, sacral neuropathy, and inadvertent needle injection of anesthetic into the fetal scalp, mother, or provider.[6-9]

APPENDIX

28F

Repair of Genital Tract Lacerations and Episiotomy

BARBARA J. REALE

The editors acknowledge Lisa Kane Low, Mary C. Brucker, Saraswathi Vedam, and Tekoa L. King, who contributed to this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Approximately 85% to 90% of nulliparous women and 60% of multiparous women sustain some genital tract laceration during vaginal birth.[1,2] These lacerations can be either minor or extensive. Lacerations to the perineum often need repair, whereas lacerations to other parts of the genitalia usually need repair only if bleeding is present. In addition, an episiotomy—a surgical incision of the posterior perineal body—can be performed to expedite birth when indicated. Repair of genital tract lacerations is an essential midwifery skill.

This appendix reviews general principles for suturing, different stitches used in repairing genital tract lacerations, and techniques for repairing common genital tract lacerations sustained at birth. A brief review of current controversies regarding different repair techniques is included. The last section reviews the technique for cutting an episiotomy. Genital tract lacerations are categorized according to the extent of tissue and muscle involvement, as noted in Table 28-10. Lacerations are spontaneous events; in contrast, an episiotomy is intentional.

Figure 28F-1 illustrates the general anatomy of a perineal laceration. The anatomy that can be disrupted includes the skin, vaginal mucosa, hymenal ring, fourchette, bulbocavernosus muscle, transverse perineal muscle, and—if the laceration extends into the rectum—the external rectal sphincter, internal rectal sphincter, and rectal mucosa.

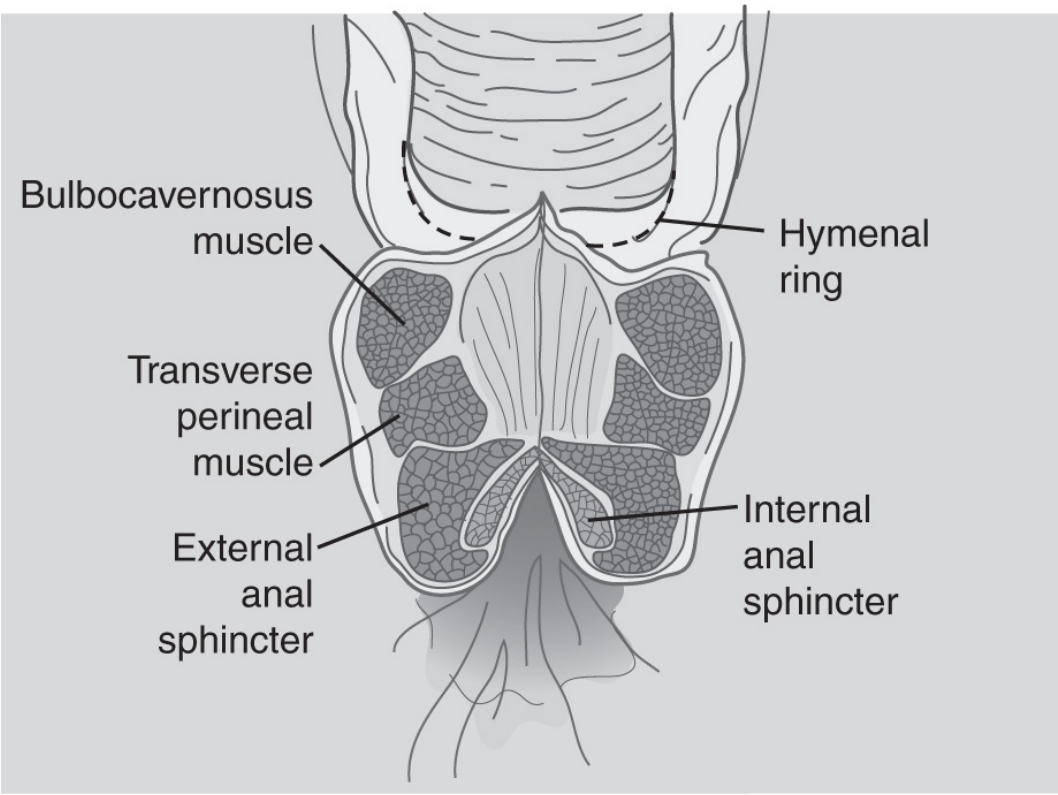

Figure 28F-1 Anatomy of a perineal laceration or midline episiotomy.

Equipment for Repair of Genital Tract Trauma

- Sharp scissors
- Sterile gauze sponges (4 × 4)
- Needle holder (also termed a needle driver)
- Tissue forceps with and without teeth
- Suture
- 1% lidocaine *without* epinephrine
- Syringe and 18-gauge needle for lidocaine
- 22-gauge needle for local infiltration

Optional as needed:

- Iowa trumpet and needle for pudendal block
- Sims retractor

Third- or fourth-degree laceration:

- Gelpi retractors
- Allis clamps

General Principles and Suture Technique

Repair of a genital tract laceration or episiotomy accomplishes three goals: (1) hemostasis, (2) return to functional integrity, and (3) cosmetic repair. Multiple sources exist electronically on the Internet that demonstrate various aspects of perineal laceration repair for learners who need a visual demonstration. Active practice using models and under direct supervision of an experienced midwife or physician cannot be underestimated.

Achieving Hemostasis

Hemostasis must be achieved first before a wound is closed. Blood clots increase the inflammatory reaction and serve as a culture media for bacteria. Large clots can cause tissue necrosis by creating pressure on adjoining tissues.

Hemostasis is accomplished by tying off bleeding vessels, by eliminating dead space, and by using techniques that minimize trauma to the tissue. The following techniques also aid in promoting hemostasis:

1. Gently probe the depth of the wound before suturing to identify the true depth that needs repair beneath the mucosal layer.
2. Start any line of suture at least 1 cm beyond the apex of the wound to include any retracted blood vessels.
3. Use stitch types that facilitate hemostasis in the most vascular areas, such as the continuous locked or blanket stitch.
4. Use an atraumatic (tapered) needle instead of a cutting needle.

Promoting Wound Healing

Wound healing involves three phases: inflammation, proliferation, and maturation.[3] Although healthy women tend to heal well, it is critical that aseptic technique is maintained to avoid the risk of infection. Asepsis may require changing gloves following the birth and redraping the area if necessary to create a sterile field; using an extra sterile glove over the sterile glove(s) already on an examining hand when checking the rectum and discarding the extra glove immediately after use; and careful placement of suture on the sterile field as the process of the repair is conducted.

During the process of wound repair, the following techniques promote wound healing:

- Use the smallest suture, suture gauge, and needle size that are needed.
- Use an atraumatic round needle.
- Precise approximation of tissues: Place sutures once where desired. Do not remove and replace sutures to obtain a more perfect result.
- Do not place sutures too close together or make them too tight. Tissue strangulation can result from too-tight sutures.
- Avoid repeated unnecessary sponging, prodding, and probing of the wound. Dab—do not wipe—to avoid creating additional trauma to the tissue.

- Avoid use of instruments that crush tissue.
- Remove blood clots and debris before closure.
- Establish visible hemostasis before closure to avoid formation of hematomas.
- Ensure closure obliterates all dead space.

Selection of Suture Material

Types of suture include standard synthetic suture, rapidly absorbing synthetic suture, glycerol-impregnated catgut suture, standard synthetic suture with rapidly absorbing synthetic monofilament suture, and catgut.[4] Synthetic sutures are preferred, as they are associated with less pain in the immediate postpartum period.[3,5] Synthetic suture is also less likely to require removal and resuturing when compared to catgut.[3,5] Catgut has the additional disadvantage of causing a marked tissue inflammatory reaction that produces edema, which places tension on the sutures and may cause tissue necrosis. Ultimately scarring can result, which results in a weaker functional repair. The two most common absorbable synthetic suture types are polyglycolic acid (Dexon, Davis & Geck Ltd., United Kingdom) and polyglactin 910 (Vicryl, Ethicon Ltd., United Kingdom).

Selection of Suture Gauge and Needle Type

Muscle heals by deposition of scar tissue and requires a stronger suture than does other tissue, which regenerates itself. The larger the gauge number, the finer the suture (e.g., 4-0 is finer than 6-0 or 8-0). The suture gauges used for various conditions are listed in **Table 28F-1**.

Table 28F-1 **Suture Gauge and Common Sites for Use of Suture Material**

	Gauge	Common Repair Sites	Usual Types of Stitches
Thinner ↓ Thicker	4-0	Clitoral lacerations	Continuous, interrupted
		Shallow periurethral lacerations	Continuous, interrupted
		Anterior wall of rectum (repair of fourth-degree laceration)	Continuous, locked
	3-0	Vaginal mucosa	Continuous, locked
		Deep periurethral lacerations	Subcutaneous, continuous
		Pelvic muscles that are not extensive	Deep interrupted
	2-0	External anal sphincter	Continuous, deep interrupted
		Cervical lacerations	Continuous, deep interrupted
		Lateral wall lacerations	Continuous, deep interrupted
		Deep pelvic muscles	Deep interrupted

The use of an atraumatic or tapered round needle is recommended instead of a cutting needle to reduce tissue trauma and the risk of increased hemostasis (**Figure 28F-2**). A cutting needle is triangular in shape, and each edge has a sharp surface; in contrast, the atraumatic needle is a round needle with a tapered point. The latter moves through soft tissues more easily than a

cutting needle and is less likely to lacerate a blood vessel. The anatomy of a needle is identified in **Figure 28F-3**.

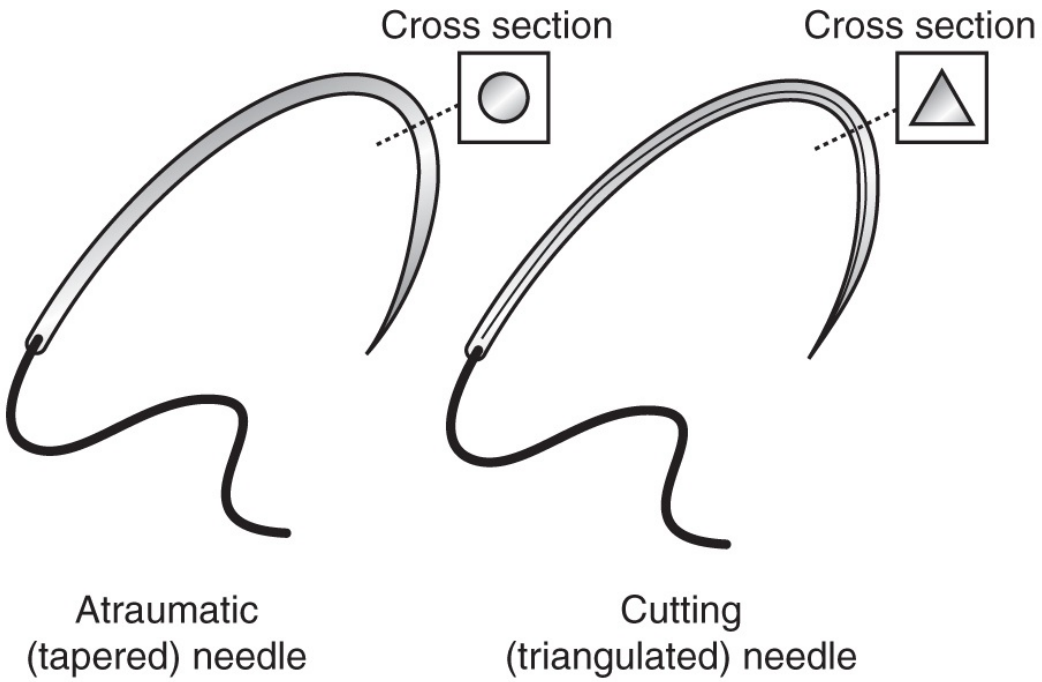

Figure 28F-2 Types of curved needles usually attached to suture material (swaged).

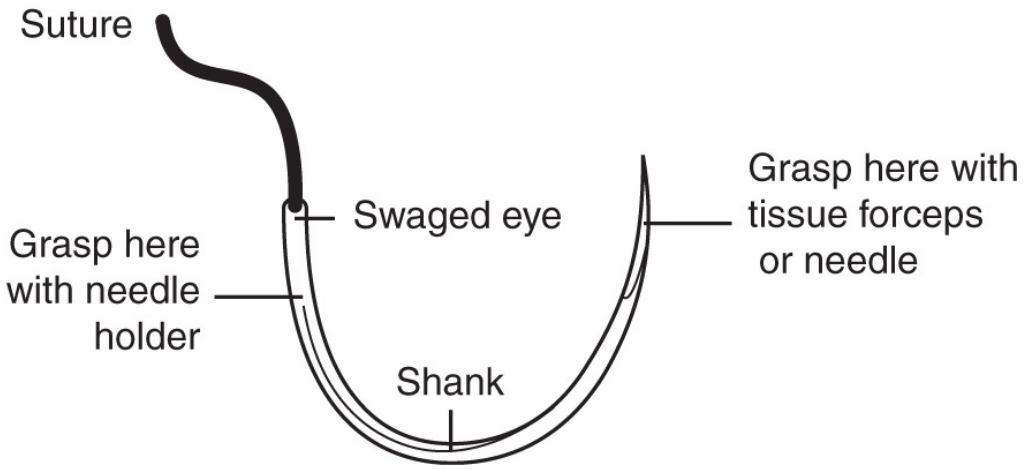

Figure 28F-3 Anatomy of a needle.

Suturing

Key Points

1. General suturing techniques and appropriate sutures for different tissue types should be reviewed before beginning the repair. The tissue should be carefully visualized and

landmarks identified.

2. Excess suture can be gathered up in the palm of the hand holding the needle holder, so as to prevent the length of suture from dangling over or dragging across areas of contamination.
3. The needle is clamped by the tip of the needle holder so that the plane of the curve of the needle is perpendicular to the plane of the needle holder. Clamp the needle just proximal to the junction of the needle and the suture.
4. Do not clamp the needle holder at the junction of the needle with the suture, or on the suture, to avoid weakening the suture.
5. The needle holder is controlled by wrist action. It can be held so that the thumb holes are in the palm of the hand and secured by the ring and little fingers. With this positioning, the thumb and middle fingers are on either lateral side of the shaft, with the index finger on one side (usually the upper) of the broad side of the shaft (rather than placing fingers through the holes). Some midwives refer to this placement as "shaking hands" with the needle holder (**Figure 28F-4)**.
6. Because of the need for universal precautions, the midwife always should use forceps to grasp or "pick up" the point of the needle, once it has come through tissue, to guide it to completion of the stitch.
7. The needle should be guided through tissue along the angle of its curve. When following the circle of the needle, rather than pulling it straight up, the suture will lie in the smallest space possible, a track left by the needle. If the needle is pulled straight, its arced shape will enlarge the space it creates in the tissue and the suture will lie in a larger track, which may result in a less stable stitch, or collection of blood and fluids. Turning the wrist to have the same angle as the needle promotes smooth movement.
8. Suturing is begun by holding the needle with its curved midportion turned so the tissue can be entered with the point of the needle perpendicular to the tissue. Therefore, the hand holding the shaft of the needle holder will be positioned so that the back of the hand is up and then further pronated as the needle point is positioned for entry. As the needle enters the tissue, the wrist is rotated approximately 180° so that the needle follows the necessary directional path for exit, completing the stitch.
9. As the point of the needle emerges, it should be grasped either by tissue forceps (without teeth) or by releasing the needle holder from its original position and repositioning the needle holder to grasp the emerging point (**Figure 28F-5**). Tissue forceps always should be used when sewing deep to moderately deep wounds. In such a case, the amount of tissue is often large enough that it is impossible to release the needle holder and grasp the other end of the needle, without losing the needle in the tissue. When shallow stitches are being made, such as subcuticular stitches, the needle holder may be released and reclamped to the other end of the needle, to complete the stitch, without concern for the needle being retracted into the tissue. Do not grasp the point of the needle with fingers—doing so may cause a needle puncture.
10. Avoid an excessive number of needle punctures, an unnecessary number of stitches, placement of stitches in very close proximity, and misplacement of stitches that have to be removed. Excessive suture in the wound slows the healing process by causing an

inflammatory reaction to foreign material.

Figure 28F-4 One method for holding a needle holder.

Knots

A square knot is the basic knot used for repairing an episiotomy or a laceration (**Figure 28F-6**). A square knot results after a left-handed overhand knot is created, followed by a right-handed knot. Most experts advocate completing not only the square knot, but also one more action to ensure that the stitch does not come undone. This knot, which may be colloquially termed a “knot and a half,” is made in case either the first or third action becomes loose or the suture dissolves more rapidly than anticipated. In either case, the complete square knot would remain.

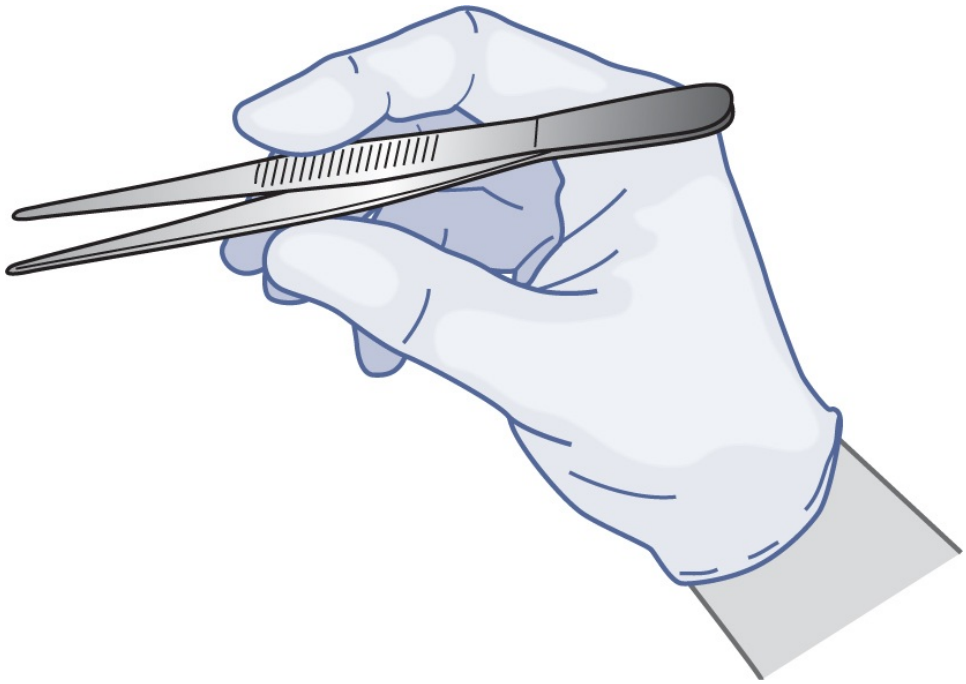

Figure 28F-5 Tissue (pickup) forceps without teeth.

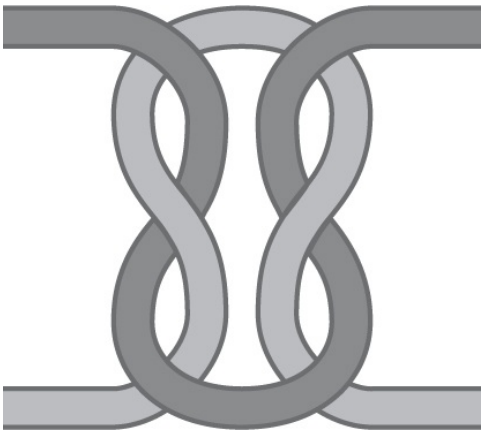

Figure 28F-6 Square knot.

A square knot can be tied by hand, by instrument, or by both, as all of these options can ensure that the knot is appropriately tied and placed flat against the tissue. Instrument ties are recommended, as they are safest for the provider. Another advantage of an instrument tie is that the knot can be tied with a short suture length, whereas a hand tie requires longer suture to complete tying the knot.

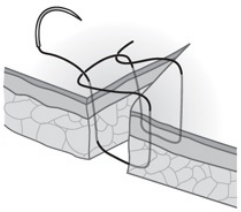
Attaining skill in tying knots requires practice. Multiple resources on this topic exist on the Internet, including a variety of digital recordings illustrating how to tie a knot by hand or instrument in real time (a topic beyond the scope of this appendix). Knot-tying boards are available, although not essential for practice.[6]

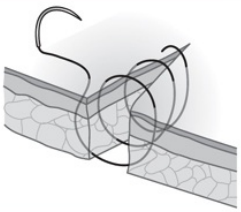
Key Points for Tying Knots

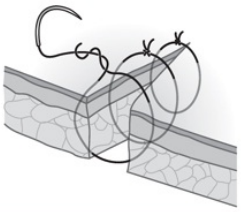
1. The knot should be as small as possible to minimize the use of excessive suture material; in turn, the ends should be as short as possible. Extra ties do not necessarily provide extra security, but they do provide additional and unwarranted suture material that can irritate healing tissue.
2. Friction between the strands, also called sawing, should be avoided as much as possible because it can weaken the integrity of the suture.
3. Crimping of the suture should be avoided except when grasping the free end of the suture during an instrument tie.
4. Sutures used simply to approximate tissue should not be tied with excessive tension because this condition may contribute to tissue strangulation.
5. As the knot is tied, tension should be as equal as possible on each step and the final tension should be made as nearly horizontal as possible. The midwife may need to change personal position to tie the most effective knot.

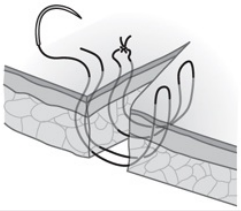
Types of Stitches

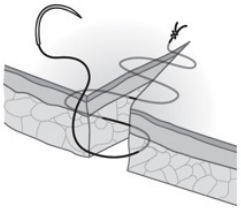
Challenges in any discussion of the types of stitches used in repairing genital tract lacerations include the existence of many, often minor, variations to a basic technique and multiple names for both the same stitch and those variations. The most commonly used stitches—continuous, continuous locked, interrupted, subcuticular, figure of eight, and crown—are illustrated in **Figure 28F-7**. The description of each of these techniques in this section usually assumes a right-handed practitioner; the direction should be reversed if suturing in a left-handed manner.

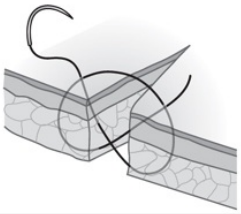


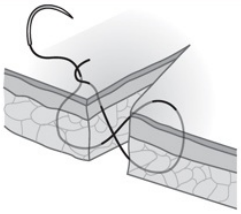












Suture	Alternative nomenclature	Illustration
Continuous locked	Blanket	
Continuous	Running	
Interrupted		
Double interrupted for third-degree laceration		
Subcuticular	Mattress

Figure 28F-7 Sutures.

Continuous Locked (Blanket) and Continuous (Running) Stitches

A continuous stitch is often called a running or “whip” stitch. However, each stitch can also be

locked to provide additional security. This locking is the differentiating factor between the two most common types of continuous stitches.

1. The needle is inserted into the right side of the wound and brought through the incision to emerge on the left side of the wound. The amount of tissue on each side should be approximately the same. Based on the amount of the tissue, it may be advisable to bring the point of the needle out into the midline of the wound to verify positioning before continuing to the left side.
2. An anchoring knot is tied on the left side of the stitch and one end is cut short.
    a. For a continuous locked (blanket) stitch, the point emerges in front of the previous stitch but under a loop or section of the suture. As the needle exits the tissue, the section of suture remains behind it. This maneuver locks the stitch.
    b. For a continuous (running) stitch, the needle point emerges in front of the previous stitch—*not* under a loop or section of the suture.
3. The needle and suture should be guided through the tissue, following the curve of the needle.
    a. A continuous locked (blanket) stitch is secured or locked along the left side of the wound line in right-handed suturing and locked along the right side of the wound in left-handed suturing.
    b. A continuous (running) stitch is made by repeating stitches from right to left (or left to right if left-handed) approximately 0.5 to 1 cm apart, with insertion and exit points being in parallel. The needle enters the tissue on the one side and carries the suture under and perpendicular to the line of the laceration across the laceration to the opposite side, where it exits into the vaginal mucosa. The suture is then carried from the exit point, diagonally across the uppermost surface of the wound to a reentry point 0.5 to 1 cm from the last entry point, and then repeats the traverse under the wound perpendicularly.

These steps should be repeated until the wound is closed.

Interrupted Suture

An interrupted stitch consists of a single stitch and knot. Both ends of the suture are cut short.

1. The needle is inserted into the side of the wound and brought through the wound to emerge on the other side of the wound, directly across from the origination. The suture should not be drawn completely to the end of the suture, as an end is needed for tying.
2. The amount of tissue picked up by the needle on each side of the laceration should be approximately the same, unless the depths of the sides of the wound are uneven (e.g., in a mediolateral episiotomy). If this is a deep stitch, with a large amount of tissue to bring together, it is advisable to bring the needle out in the midline of the wound and then take another stitch into the other side of the wound. This approach will verify positioning and ensure that the needle grasps the appropriate amount of tissue on each side.
3. Tie a square knot using both ends, by hand or with instruments, to secure the stitch. If the

interrupted stitch is used for deep muscle, the needle and suture should include the apex of the wound to avoid leaving any unsutured dead space behind the closed wound.

Separate interrupted stitches should be inserted as needed by following these steps.

Subcuticular (Mattress) Stitch

A subcuticular stitch is a buried horizontal stitch used for closing the subcuticular perineal skin during a laceration or episiotomy repair so that the suture is not visible on the skin.

1. An anchoring stitch is placed in the appropriate site going through the skin if necessary, a knot is tied, and one end is cut short. When subcuticular sutures are used to close the perineum during repair of a second-degree laceration, this anchoring stitch is not needed because the subcuticular stitches will follow a series of running continuous stitches.
2. Use of tissue forceps with teeth, to hold the skin and adjacent tissue stable while placing a stitch, may be helpful. Pick up the tissue ahead of where the needle will enter and exit.
3. Insert the needle on one side of the incision. Unlike with other stitches, this insertion is shallow—"one cell layer" deep, although it is difficult to ascertain that benchmark. The suture is placed immediately below the skin layer and will run parallel to the line of the wound under the skin.
4. Gently guide the suture through the tissue for approximately 0.5 cm in length.
5. Make the next stitch in the same manner on the opposite side of the wound. The entry point on this side should be directly across from the exit point of the preceding stitch on the opposite side of the wound. If exit and entry points are not directly across from each other, the skin will appear "bunched up." Careful placement will result in smooth, even closure.

These steps are repeated until the wound is closed.

Figure of Eight Stitch

A figure of eight stitch is used to provide hemostasis and tie off actively bleeding vessels. It is also used for securing the rectal sphincter muscle.

1. Start the stitch by entering the tissue on one side behind the bleeding vessel and bringing it out on the other side, also behind the bleeding vessel. This suture should not be tied or cut. An end for tying should remain loose.
2. Continuing with the same needle and suture, create a second, parallel stitch in front of the bleeding vessel, starting on the side in front of the vessel where the first stitch was placed and emerging again on the other side in front of the vessel.
3. Create another end for tying by cutting the needle off from the suture. The two ends of suture can be tied diagonally across the tissue surface, creating a figure of eight. The suture constricts the bleeding vessel within its configuration.

Crown Stitch

The crown stitch is used to reapproximate the bulbocavernosus (bulbospongiosus) muscle. This step restores the anatomy of the perineum, introitus, and labial junction at the mucocutaneous junction. When the bulbocavernosus muscle is torn, the ends usually retract superiorly and posteriorly. The crown stitch is placed in a manner that securely grasps each end, and brings both ends down and medial, to approximate them.

1. Begin by entering the tissue in an upper diagonal slant at the upper-left side of the wound line at the junction of the perineum and the vagina. Adequate space should be allowed away from the edge of the incision to enable subcutaneous continuous stitches and potentially a subcuticular closure over the completed crown stitch. Do not tie or cut the suture.
2. Direct the needle so that it follows a sequence of moving upward, then laterally, downward, and medially so that it exits in the same plane, but posterior to the original entry site. Experience is essential to perform this technique well because the amount of lateral thrust must be just enough to reach the retracted cut end of the bulbocavernosus muscle if possible. The more lateral tissue obtained, the more vascular the area and the higher the risk of a potential hematoma. Grasping the two ends of the suture a short distance from the tissue and gently pulling them can provide verification that the bulbocavernosus muscle has been included in the suture. If the bulbocavernosus muscle has been sutured, the entire left-side labia will be pulled.
3. Insert the needle into the tissue at the right side of the wound directly across from the exit point on the left side. Direct it in a manner that mirrors the action in Step 2. The correct placement through the bulbocavernosus muscle can be ascertained using the same technique as described in Step 2.
4. After cutting off the needle, the two ends of suture should be next to each other and are knotted, with the ends cut short. Care must be taken to only closely approximate the muscle in repairing it; pulling and suturing the two sides together too tightly may result in increased scar tissue and dyspareunia.

Repair of a Second-Degree Laceration or an Episiotomy

Following are the steps that are used to repair a second-degree laceration or episiotomy. As with several other midwifery skills, this is only one of several possible methods. This method includes both continuous and interrupted stitches. Research has shown that closures dependent only on interrupted suturing techniques are associated with more pain.[7]

Repair of midline and mediolateral episiotomies is essentially the same. However, in a mediolateral episiotomy, the medial aspect of the incision tends to retract more than the lateral aspect, indicating the need for special care to avoid the rectum when suturing. In addition, the stitches for this repair follow the incisional line and are performed at a slant, rather than straight across as done for repair of a midline episiotomy or laceration, with slightly more tissue on the lateral side than on the medial side. When completed, the stitches may be closer

than for a midline closure. Sometimes a laceration may occur at an angle, and the same comments may apply.

Key Points Prior to Repair

1. An aseptic field must be established and meticulously maintained. Establish this field by clearing away soiled materials, irrigating or cleansing soiled skin areas, and, if needed, placing clean or sterile drapes under the buttocks.
2. Good visualization of the area of repair is critical. Lighting and positioning may need to be adapted. If a woman is positioned using stirrups, the time should be limited to less than 90 minutes to decrease the risk of impaired circulation or thrombophlebitis.
3. Visualize the vulva, labia, vestibule, vaginal walls, cervix, and perineum to identify all sites of bleeding and tissue disruption prior to beginning the repair.
4. Identify and tie off any actively bleeding vessels with a figure of eight stitch prior to repairing the main laceration.
5. Identify the depth of the lacerations in all directions. Shallow lacerations usually do not include muscle, but occasionally the muscle is nicked. In these instances, where a muscle is mostly intact, a well-placed continuous suture can give enough support to the muscle to facilitate well-approximated healing. Deep lacerations bifurcate muscles. The two ends of a bifurcated muscle can be properly approximated with well-placed interrupted sutures. When severed perineal muscles are not well approximated, the end result may be weakness and a gaping introitus.
6. Provide appropriate anesthesia. Local infiltration or a pudendal block can be performed when needed.
7. Through the procedure, maintain good communication among the woman, the midwife, and other support personnel as appropriate.

Technique for Repair of Second-Degree Perineal Laceration or Episiotomy

1. A sponge or other absorbent material that has a tail, which remains outside the vagina, may be inserted as a tampon if necessary to maintain a dry field. Do not use a tampon without a tail. Some portion should always be visible outside of the vagina so removal when the procedure is over is assured.
   a. Insert two fingers along the posterior vaginal wall, apply downward pressure, and slide the rolled tampon against the posterior aspect of the fingers toward the posterior fornix of the vagina.
   b. Secure the tail with a clamp to a drape where it can be seen and will not be forgotten or left in the vagina when the repair is complete.
2. Check the integrity of the anal sphincter. Feel the depth of the defect and ascertain that the anal sphincter is intact. Place a second glove over the examining hand if necessary to insert an examining finger into the anus to determine the integrity of the sphincter and rectal mucosa; discard this glove immediately after examining the rectum. Probe the tissue gently to avoid causing additional trauma.

3. Before starting to sew, gently support the tissue so that it falls together naturally and identify key landmarks that will be anatomically approximated, including the hymenal ring, apex of vaginal mucosa, mucocutaneous junction, and perineal apex. It may be helpful to use a tissue forceps with teeth to pick up one side of the laceration and carry it over to the other side to visualize how it should come together, before beginning suturing.
4. The tissue between the vaginal mucosa and rectum consists of muscle, fascia, and other tissue fibers that are collectively referred to as the recto-vaginal septum. It is repaired in stages, and in different planes. From above, sutures are placed vaginally with insertion directed down into the septum. Laterally, sutures are placed below the perineal skin, and directed inward.
5. Repair the vaginal mucosa and underlying recto-vaginal fascia: The vaginal mucosa and fascia are repaired with a 3-0 synthetic absorbable suture using an atraumatic, tapered needle with locked continuous suturing (**Figure 28F-8**).
    a. Visualize the vaginal apex by placing both fingers along the wound edges and applying gentle downward pressure. The anchoring stitch is placed approximately 1 cm beyond the vaginal apex of the wound, and provides hemostasis for any retracted blood vessels. This stitch is tied and one side cut close to the knot, leaving an approximately 0.5-cm tail.
    b. The vaginal mucosa and fascia are repaired from the posterior aspect of the wound in the vagina to the hymenal ring, using locked continuous (blanket) stitches. They should be approximately 1 to 1.5 cm apart. The first one or two stitches should be deep enough to include adequate tissue on each side of the wound to close it completely. The farther the wound extends posteriorly, the more stitches that are needed to bring the septum together, up to the level of the perineal muscles. Thereafter, the stitches should be shallower and include only the vaginal mucosa. The muscle should stay exposed so that it can be visualized and repaired.
    c. Avoid placing sutures through or over the hymenal ring, as they may cause discomfort in the healing process and subsequent dyspareunia (although proof that dyspareunia occurs is lacking). Instead, place the needle so that it locks the last vaginal stitch as it is directed downward to bring the suture from the vagina behind the hymenal ring into the perineal plane. It exits in the submucosal tissue of the wound, in the perineum.
    d. If the wound is shallow and appears to have just nicked the muscle, continuous suturing of the *subcutaneous tissue* to the apex of the perineal laceration is done as described later in this procedure. In contrast, if the wound appears deep enough to have significantly separated the perineal muscles, correct placement of deep interrupted stitches will give excellent support for an accurately reconstructed perineal body.
    e. For a deep repair, the first needle and suture are set aside, to be used again later in the subcutaneous and subcuticular repairs. It is important to “guard” the needle not in use by clamping the swaged end of the needle with the tip of the needle pointed toward and barely touching the needle holder. The needle and holder are then placed

onto a sterile drape.

6. *Muscle layer:* A layer of interrupted stitches is used to bring together the bulbocavernosus and perineal muscles. To determine the depth of suturing required, insert a finger below the vaginal mucosal area that has been repaired. If there is more than 1 cm of space below the sutured mucosa, interrupted stitches are placed to well approximate the muscles and close this space (**Figure 28F-9**).
   a. A 2-0 absorbable synthetic suture with an atraumatic needle is used for the interrupted stitches.
   b. Repair may begin with the crown stitch, to bring together the bulbocavernosus muscle (**Figure 28F-10)**. Since this muscle retracts posteriorly and superiorly, the crown stitch is best suited to grasp the large muscle ends to approximate them from top to bottom. It may be helpful to visualize a torn bulbocavernosus muscle as a tubular elastic ring with ends that retract when cut at the base. The crown stitch grasps the muscle from top to bottom on each edge.

      Some midwives choose to repair the muscles only with horizontal interrupted stitches. This preference is based upon a historical concern that a crown stitch may increase the risk of subsequent dyspareunia. Placing a horizontal stitch through the bulbocavernosus muscle may partially approximate it, particularly if the stitch goes through only the lowermost part of the muscle. No evidence exists to support one method over the other, but the integrity of this muscle clearly has functional significance.

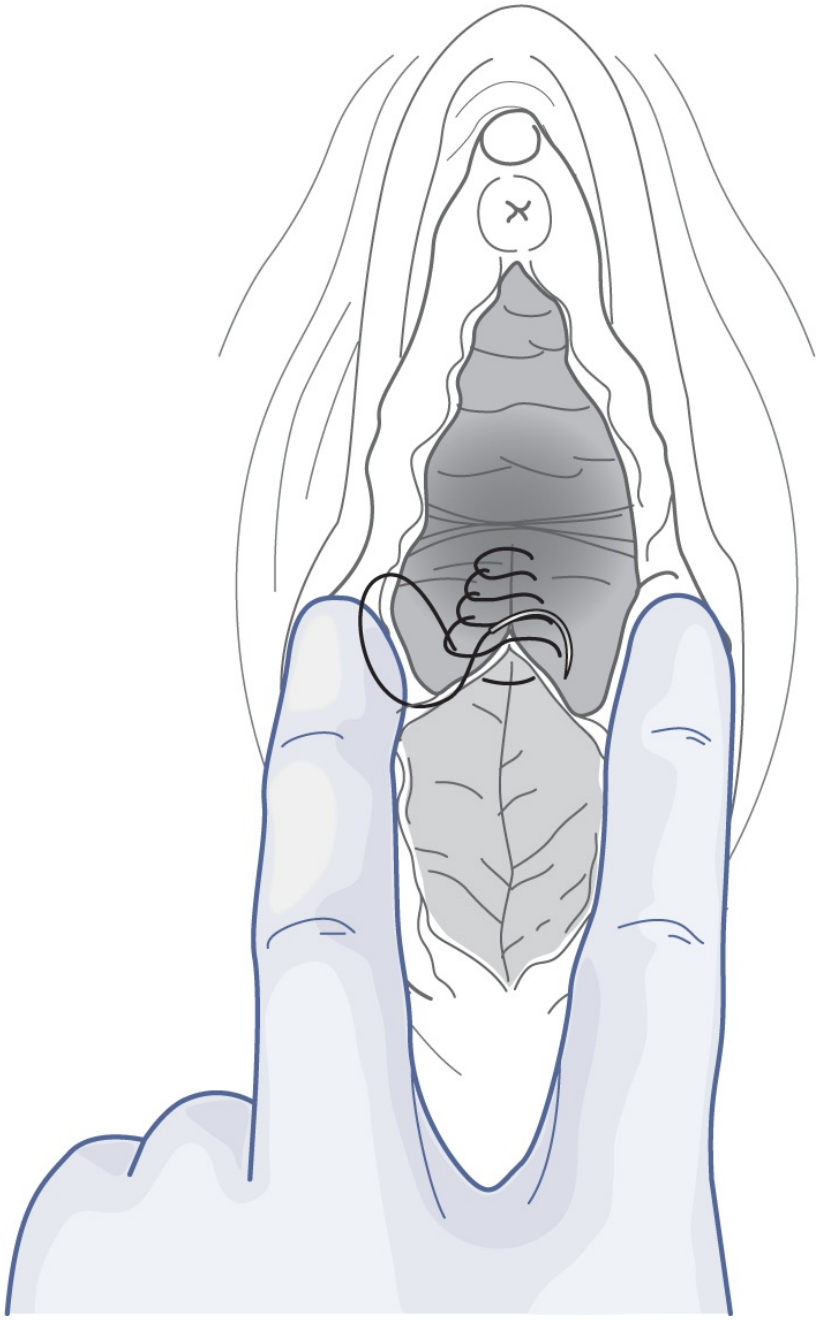

Figure 28F-8 Repair of vaginal mucosa and recto-vaginal fascia using continuous locked (blanket) stitches.

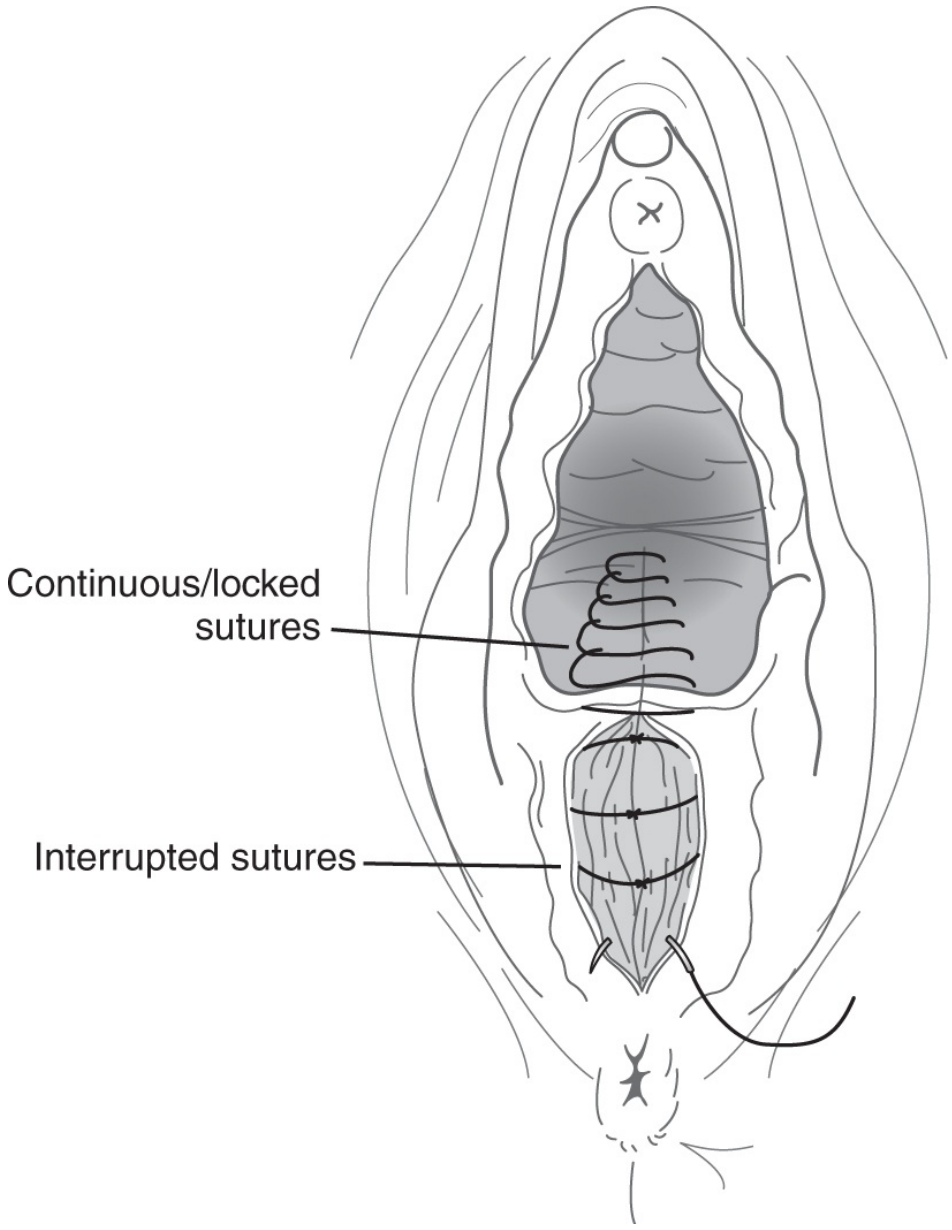

Figure 28F-9 Repair of muscles using interrupted stitches.

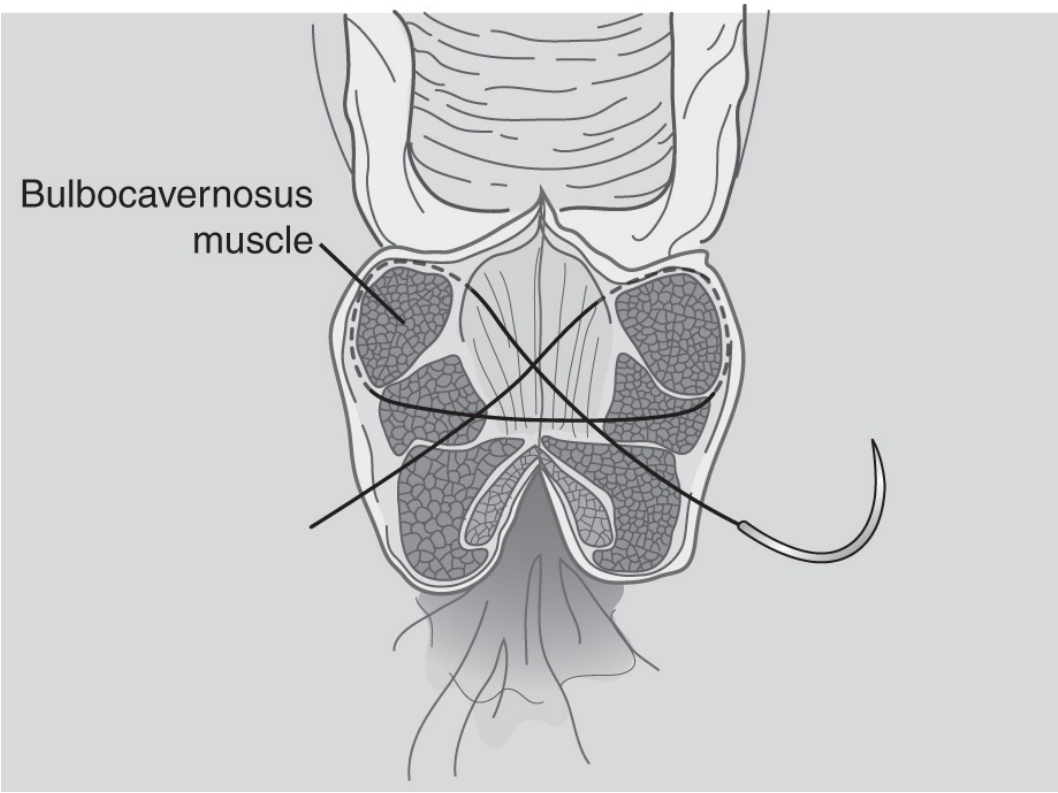

Figure 28F-10 Crown suture.

c. The perineal muscles retract laterally. Place deep interrupted stitches in a horizontal plane to ensure that the stitches do not accidentally go into the rectal mucosa. With the woman supine, the needle holder will be perpendicular to the floor and the introitus. The amount of tissue to be taken up is often too much for one bite, so the first action directs the needle to come out into the back of the defect. The needle is then grasped with a tissue forceps (without teeth) and replaced correctly in the needle holder, and a second stitch is taken to incorporate the other side. It is important that needle exit and entry points are directly across from each other.

d. After the interrupted stitches are placed, perform a rectal examination to determine whether any of the stitches can be palpated within the rectal mucosa. To maintain sterility, either a new glove is placed over the hand used for the examination and then discarded, or the single glove must be replaced. If a suture is palpated in the rectum, the repair must be dismantled until the suture is removed to prevent infection or creation of a sinus tract. The risk of a rectal suture is diminished if all interrupted stitches are placed carefully in the horizontal plane.

7. *Subcutaneous tissue*: At this point, the suture that had been set aside in Step 5 is used to repair the subcutaneous tissue under the fourchette and down the length of the laceration toward the anus. The goal is to obliterate space that would be created by closing the skin edges over a subcutaneous defect.

a. Close the perineal subcutaneous fascia using continuous (unlocked, running) stitches, as illustrated in **Figure 28F-11.**

b. Resume using the original suture that was used to close the vaginal mucosa. Close

the subcutaneous tissue with a running stich, moving down the defect toward the inferior perineal apex close to the anus. Do not bring the needle out too close to the skin, as the layer of tissue immediately under the skin will be closed with a final layer of subcuticular stitches.

c. Place stitches approximately 1 cm apart.

d. Bring the needle out in the perineal apex of the laceration.

e. Change the direction of the needle on the needle holder for the subcuticular stitches.

8. *Subcuticular stitches*: Leave sufficient and equilateral room on both sides for the final layer of continuous stitches, with the last stitch exiting at the central point of the perineal apex. This stitch should be shallow and immediately inside, but not through, the skin.

a. Perform the subcuticular, or mattress, stitch using the same suture that was used for the subcutaneous stiches.

b. Complete stitches alternatively from side to side, moving superiorly toward the fourchette. Each stitch starts exactly parallel to the point on the opposite side where the last suture emerged (**Figure 28F-12).**

i. Bring the suture across to see where to place the needle for the next stitch.

ii. Shorter stitches are usually placed at the perineal apex near the anus, whereas longer stitches can be made closer to the mucocutaneous junction.

iii. Do not pull too tightly—edges should not overlap.

c. Approximate the mucocutaneous junction exactly, and then continue a few subcutaneous stitches back toward the hymenal ring. The depth of the fourchette or space between the mucocutaneous junction and the hymenal ring varies among women. Some will require one or two stitches, and some may require as many as three or four stitches.

d. *Final knot*: Bring the needle under and posterior to the hymenal ring. The suture will now be tied with a square knot, across the laceration. The needle should next enter close to the exit point of the preceding stitch and should be carried straight under the laceration, exiting on the opposite side. Do not pull the suture through the tissue entirely, but instead leave a loop that becomes one side of the tied knot. Cut the needle off of the opposite side and tie the knot with the two ends across the laceration, just posterior to the hymen. The knot should be made securely, but not tight enough to cause tissue strangulation. Placement of the knot behind the hymen decreases the risk of discomfort for the woman.

9. After suturing, remove the tampon, if one was used. Inspect and verify the suture line is intact and without any hematoma or active bleeding along the suture lines. Other actions include ascertaining the firmness of the fundus and removing any blood clots. Depending on the circumstances, a rectal examination to rule out any rectal sutures or hematomas may be performed. Wash the perineal area, thighs, and buttocks as needed. Assist in helping the woman assume a comfortable position. Apply ice to the repaired laceration.

10. During and after the procedure, the midwife should continually communicate with the woman and family and provide anticipatory guidance and health education.

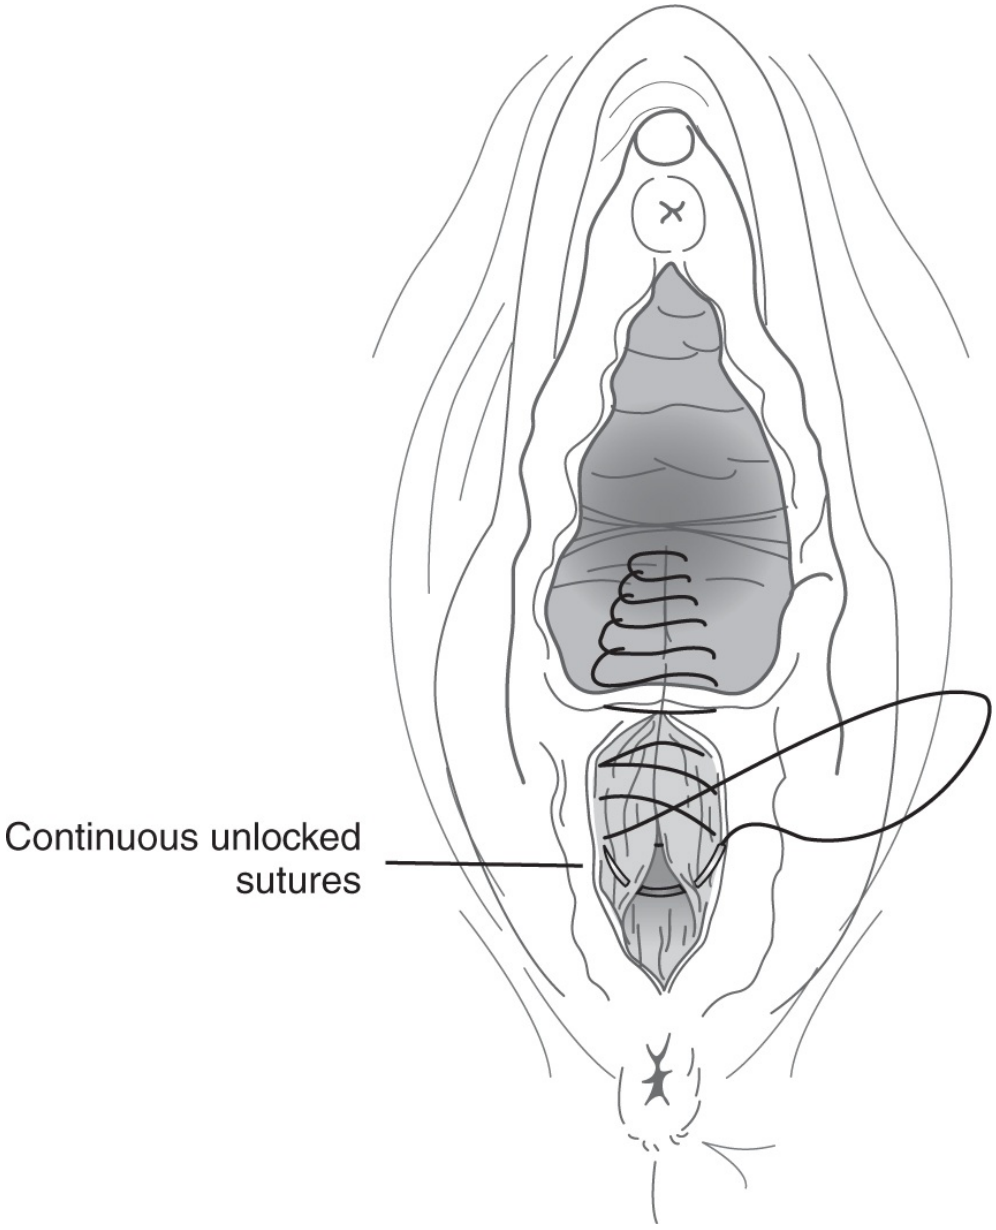

Figure 28F-11 Repair of perineal subcutaneous fascia using continuous stitches.

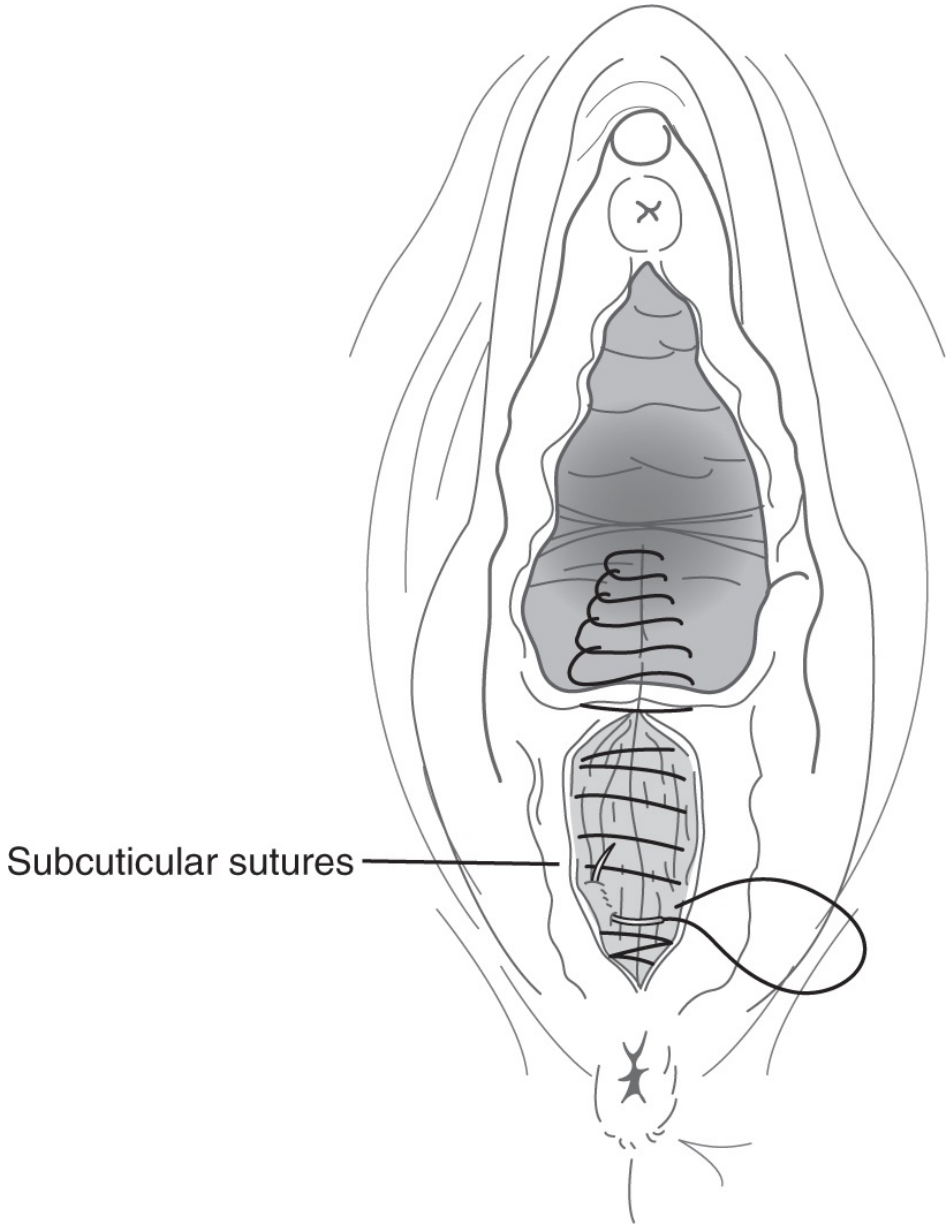

Figure 28F-12 Reapproximation of skin using subcuticular (mattress) stitches.

Repair of First-Degree Lacerations

The majority of first-degree lacerations are small skin disruptions that barely lacerate the vaginal mucosa and will heal spontaneously without suturing. More-extensive first-degree lacerations can be repaired using continuous running stitches. In some situations, a single interrupted stitch or two may accomplish closure. The midwife should assess the area to be repaired, approximate the laceration prior to suturing, and visualize all appropriate landmarks; the midwife should then plan the number of stitches that may be required in advance with the principle of placing the fewest possible to accomplish hemostasis and tissue edge reapproximation. A finer-gauge suture, such as 4-0 polyglactin on a small needle, may provide adequate tensile strength and be less traumatic.

Repair of Sulcus Tears

Sulcus tears are a type of second-degree laceration in which the vaginal mucosa and underlying tissue are lacerated along one (unilateral) or both (bilateral) sides of the posterior column of the vagina, instead of up the middle. The posterior column of the vagina is a longitudinal ridge of the inner surface of the lining extending the length of the vagina. The lateral edges of the column meld into the lateral vaginal walls and create a slight groove (sulcus) from which this type of laceration derives its name.

Significant blood loss can occur with deep sulcus tears, requiring prompt placement of figure of eight stitches. Repair of sulcus tears differs only from the repair of the vaginal mucosa if the tear is bilateral. In this event, a midline tear will bifurcate in the posterior vagina and the laceration can have a Y shape. Two apices and two separate lines of continuous locked stitches are needed to close the separate tears in the Y portion of the laceration. At their common base, one line of sutures is tied with a final stitch and a square knot, while the other line of sutures continues to draw the larger base opening together. Sulcus tears usually are deep lacerations and may require two layers of deep interrupted stitches when the deep muscle layer is repaired. To provide better access for placing the deep interrupted stitches, the vaginal mucosa may be repaired with a few stitches placed in the common base of the bilateral tear for approximation of the tissues, followed by interrupted stitches, followed by the return to the repair of the vaginal mucosa. Because of the depth and potential difficulty with visualization, a second person may be requested to assist with the repair process to aid in visualizing the wound.

Repair of Periurethral, Clitoral, and Labial Lacerations

Periurethral and labial lacerations usually are longitudinal lacerations that follow the general contour of the vestibule of the perineum. They vary in depth as well as in length, with some extending superiorly into the glans of clitoris, or inferiorly exposing the crus of the clitoris. At other times, they may be transverse lacerations extending into the labia minora and occasionally across the labia majora so that it is torn into two sections.

Repair of periurethral lacerations depends on their depth, bleeding, and the need for a cosmetic repair. Repair of any periurethral laceration close to the urethra should be preceded by insertion of a urinary catheter to prevent accidental closure of the urethra. Small superficial periurethral lacerations that are not bleeding will often heal spontaneously without stitches. Although rare, bilateral labial lacerations directly across from each other may heal together, fusing the labia. At least one of these lacerations should be closed to prevent this outcome. When significant labial edema is present, bilateral suturing and postpartum treatments such as initial application of cold packs can reduce the extent of labial edema.

When repair is indicated, most periurethral lacerations should be repaired with 4-0 suture using an interrupted technique. Prior to beginning the repair, the midwife should determine the best approach, using the least number of stitches while accomplishing reapproximation and hemostasis. There is no precise pattern or sequence of stitches to use, as each laceration is

unique.

Repair of labial lacerations may also be done with 4-0 gauge suture using an interrupted stitch. Interrupted stitches can be approximately 0.5 to 1 cm apart and should not be tied too tightly, as this tissue can very easily become edematous. Continuous sutures are not recommended for labial lacerations because they can constrict edematous tissue and distort the healing process.

Repair of Third- and Fourth-Degree Lacerations

The experienced midwife may be credentialed to perform repairs of third- or fourth-degree lacerations. Appropriate education, experience, and institutional privileges are needed in such a case.

Key Points

1. Good visualization and adequate anesthesia are essential to accurately repair a third- or fourth-degree laceration. Assistance is likely needed to secure the visualization needed.
2. Fourth- and third-degree lacerations are always repaired before repairing the rest of the perineal laceration, if present.
3. The goal is to reconstruct the muscular cylinder of the rectal sphincter, which is approximately 2 cm thick and 3 cm long.
4. The area may be irrigated with saline prior to being repaired. In contrast to practice years ago, antiseptic solutions generally are no longer employed, as they may irritate this tissue.

Repair of Fourth-Degree Lacerations

Fourth-degree lacerations involve the external anal sphincter, internal sphincter, and anterior rectal mucosa. The rectal mucosa and the internal anal sphincter are always repaired before the external rectal sphincter is repaired. After identifying the tear in the anterior rectal wall and the torn ends of the anal sphincter, the repair begins by rejoining the anterior rectal mucosa. This area is repaired in two layers with 3-0 or 4-0 polyglactin suture on an atraumatic needle.

1. The first layer starts at the internal apex and consists of a row of interrupted stitches placed in the rectal submucosa to approximate the rectal mucosa without placing stitches in the lumen of the bowel. The use of a smaller, atraumatic curved needle is essential to take smaller amounts of tissue into each stitch, thereby decreasing the risk of extending into the lumen of the bowel.
2. The second layer is the internal anal sphincter; it appears as a shiny pink, thick tissue that lies just above the rectal mucosa. It often retracts laterally and superiorly. Repair is made with a continuous technique using 3-0 polyglactin suture. This repair also starts at

the internal apex and is brought out to the cutaneous junction, where it is tied off.

3. After verification that no sutures are in the rectal lumen, repair of the external anal sphincter as described in the next section, followed by standard repair of the laceration or episiotomy, is completed. Special care must be taken in rebuilding the muscle layers of the perineal body, which have been totally lacerated.

Repair of Third-Degree Lacerations

A third-degree laceration differs from a fourth-degree laceration in that it does not include the rectal mucosa. Otherwise, repair of the anal sphincter is the same for both types of lacerations.

1. Identify the torn external anal sphincter. As the torn ends retract, they are found flush with, or as dimples in, the lateral walls at the bottom of the perineal aspect of the wound near the surface. The muscle fibers of the sphincter are visually different from the surrounding fascia. Often one side is dimpled, and the muscle can be visualized emerging from the other side.
2. Grasp both torn ends with an Allis clamp and pull them toward each other, causing them to meet. The suture of choice is 2-0 synthetic, absorbable suture. Some midwives prefer to first anchor a 3-0 absorbable suture within the inferior apex of the skin extension of the laceration and take a few subcuticular stitches in the posterior anal capsule, then lay this suture aside until the end. This approach is intended to avoid later difficulty in repairing the subcuticular area over the rectal sphincter, as it is sometimes difficult to visualize this apex after repair of the sphincter.
3. Repair a lacerated external anal sphincter with either doubled interrupted stitches or a figure of eight stitch after approximating the torn ends grasped by the Allis clamps.
   a. Inclusion of the anterior and posterior fascial layers surrounding the sphincter muscle strengthens the repair.
   b. The internal and external sphincters may both be lacerated. Knowledge of the anatomy is essential to identify the anal sphincter.
   c. The sphincter can be repaired by one of two methods: The first places the torn section “end to end” and the second uses an “overlapping” technique (**Figure 28F-13)**. The overlapping technique is superior in that it is associated with less fecal incontinence and pain.[7-10] The overlapping method is recommended for a complete tear but cannot be used for an incomplete tear (grade 3a or partial-thickness grade 3b).[7]
   d. Technique for a doubled interrupted stitch:
      i. Put the needle into the right side of the muscle and bring it out in the left side of the muscle.
      ii. Put the needle in the left side of the muscle near where it came out and bring it out in the right side.
      iii. The suture now has two strands and will be tied off on the side where it was started.
   e. *End-to-end repair*: Place four doubled interrupted sutures, starting at the posterior

aspect as illustrated in **Figure 28F-13A**, with one in each quadrant at the 6 o'clock, then 9 o'clock, then 12 o'clock, and then 3 o'clock positions.

f. *Overlapping technique*: Using the Allis clamp, overlap the ends of the sphincter and place three doubled interrupted sutures in both parts of the muscle where they overlap (**Figure 28F-13B**).

4. After repairing the sphincter and before continuing with the remainder of the repair, perform a rectal examination to confirm that sutures have not been placed in the rectal mucosa as previously described. Repair of the laceration or episiotomy then continues in standard fashion.
5. When a woman has a third- or fourth-degree perineal laceration, it is common practice to order stool softeners, oral analgesics, and sitz baths for her initial postpartum recovery. Antibiotics to prevent wound infection are considered on an individual basis.[7]

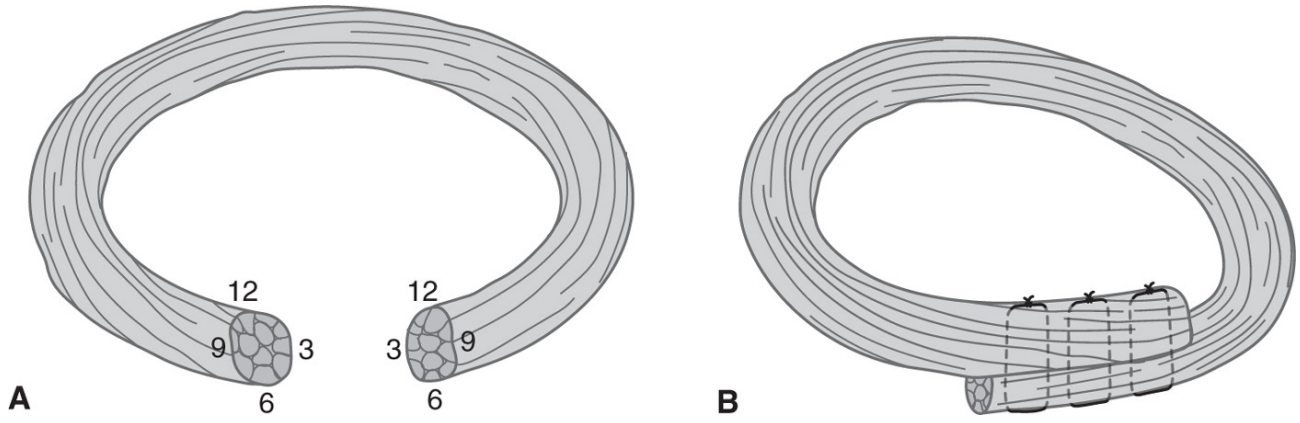

Figure 28F-13 Repair of anal sphincter. **A.** End-to-end technique. **B.** Overlapping technique.

Repair of Cervical Lacerations

Cervical lacerations can be difficult to identify and can bleed extensively. An assistant may be invaluable in this situation to hold the retractors that will enable good visualization.

Key Points

1. Good visualization is necessary, including effective use of the ring forceps on the cervix to bring the cervix and its laceration into full view, and a well-contracted uterus so any potentially obscuring bleeding is minimal (**Figure 28F-14).**
2. If an assistant is not available, use of an instrument such as a Gelpi or Sims retractor can provide better visualization. Since cervical lacerations can extend into the lower uterine segment, it is critical to be able to visualize the apex with certainty.
3. Anesthesia will be of benefit and allow relaxation that will promote better visualization.
4. Cervical lacerations more than approximately 1 cm in length or a laceration of any length that is bleeding should be repaired.

5. Cervical lacerations are repaired with 2-0 absorbable synthetic suture.

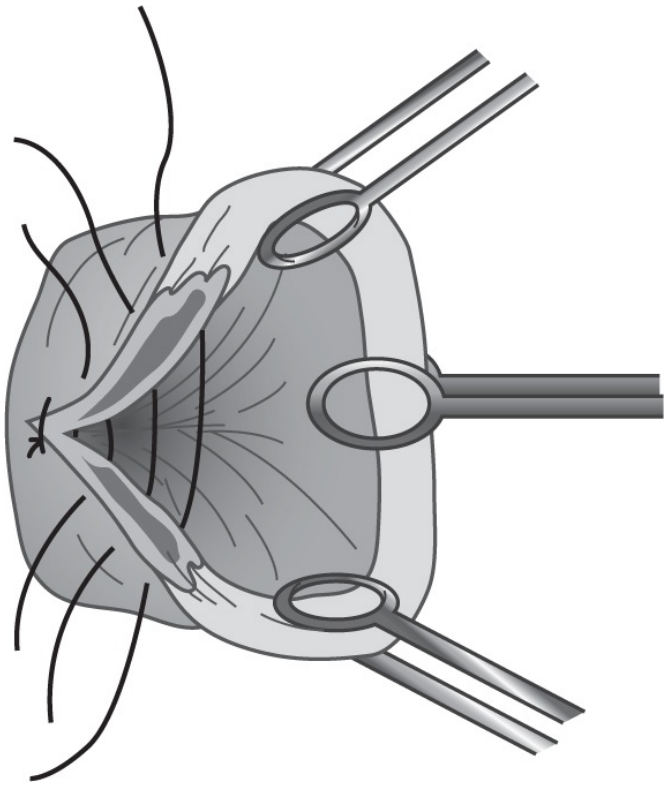

Figure 28F-14 Repair of cervical laceration using interrupted stitches.

Steps to Repair Cervical Lacerations

1. Approximation of the two sides of the tear is facilitated by the placement of a ring forceps on each side of the laceration. The forceps should be placed close enough to the edges to be of use, but far enough away from the edges that the stitches can be taken without sewing through the ring of the forceps.
2. Cervical lacerations are repaired with interrupted stitches, a continuous stitch, or a continuous locked stitch if additional hemostasis is required.
3. The first stitch should be placed approximately 1 cm above or beyond the apex of the laceration to include any retracted blood vessels.
4. Care should be taken in the placement of each stitch approximating the two sides of the tear so that only the sides of the wound are included in the stitch, thereby maintaining the patency of the cervical canal.

Controversies Regarding Laceration and Episiotomy Repair

Controversy has emerged about when to repair genital lacerations versus when to allow them to heal spontaneously. Because every laceration is unique, meaningful evidence has been

difficult to find regarding this question. In general, if the edges of the laceration appear to be well approximated when the tissue is not being handled or when the woman's legs are relaxed in a natural position, then the use of suture for repair may be avoided. Today, some professionals question whether even a second-degree laceration might heal in that manner, but available evidence on this topic is scant and inconsistent.[11]

To Repair Skin Edges or Not to Repair Skin Edges

Some authors have suggested that leaving the skin edges unsutured may result in less pain or dyspareunia, as the sutures themselves can cause irritation. A randomized trial of two-layer versus three-layer repair found that leaving the skin edges unrepaired does result in less pain and dyspareunia at 3 months postpartum, without disadvantages such as infection or repair breakdown.[12]

Episiotomy

Multiple randomized trials and a Cochrane meta-analysis have demonstrated that routine episiotomy is associated with an increased risk for severe perineal lacerations.[13] Consequently, this procedure is no longer a standard practice at all births.

Yet, because every birth is unique, cutting and repair of an episiotomy is a skill to be included in the repertoire of a midwife so that, when needed, it can be performed competently. An understanding of perineal anatomy is critical to the discussion of episiotomies/lacerations, and relevant information can be found in the *Anatomy and Physiology of the Female Reproductive System* chapter.

Episiotomies should be discussed with women prior to labor so they are aware of the indications and the procedure should it become necessary. The one accepted indication for an episiotomy is a need to expedite birth secondary to fetal bradycardia or other fetal heart rate pattern that suggests a significant risk of newborn acidemia. Other suggested but controversial indications include operative birth, suspected shoulder dystocia, and short perineum (with a mediolateral episiotomy to avoid a spontaneous fourth-degree laceration).

Key Points: Preparation

1. During labor, when it becomes apparent that an episiotomy may be necessary, the midwife should discuss the indication and recommendation with the woman and her support persons. Continuous communication as the procedure is performed informs the woman of events, especially if she has regional anesthesia and impaired sensation.
2. Appropriate equipment should be available.
3. Anesthesia is a prerequisite before an episiotomy is performed, and the level of anesthesia should be appropriate for the extent of surgical repair. Although nitrous oxide or parenteral opioids may be useful as analgesia, an epidural or a pudendal nerve block will be more effective. Under some circumstances, local infiltration may be performed prior to cutting an episiotomy, although this intervention may distort tissue and cause

edema. A description of the techniques for local infiltration and pudendal block can be found in Appendix 28D and Appendix 28E, respectively. A woman's allergies may preclude use of some anesthesia methods.

Midline Versus Mediolateral Episiotomy

Two types of episiotomy are performed: midline incision and mediolateral incision. The midline episiotomy is more commonly used in the United States.

Midline Episiotomy

The midline (or median) episiotomy has a vaginal apex at the central tendinous point of the perineum and separates the bulbocavernosus and superficial transverse perineal muscles. Depending on the depth of the cut, the deep transverse perineal muscle may also be cut into two sides. The perineal apex is above the anal sphincter.

The primary advantage of a midline episiotomy is ease of repair and better cosmetic result. Although retrospective studies of postpartum pain have found that midline episiotomies are associated with less pain than mediolateral episiotomies, prospective studies have not found a significant difference. Because the inferior apex of the midline episiotomy is directly above the rectal sphincter, extension into a third- or fourth-degree laceration is possible.[14]

Mediolateral Episiotomy

A mediolateral episiotomy also has a vaginal apex at the central tendinous point of the perineum. This incision cuts through the bulbocavernosus and the superficial and deep transverse perineal muscles, and into the pubococcygeus (levator ani) muscle. Whereas a midline incision is directly anterior–posterior, the mediolateral is cut on the diagonal (right or left) starting at the midline of the posterior fourchette, with the points of the scissors directed right or left toward the ischial tuberosity on the same side as the incision (**Figure 28F-15).**

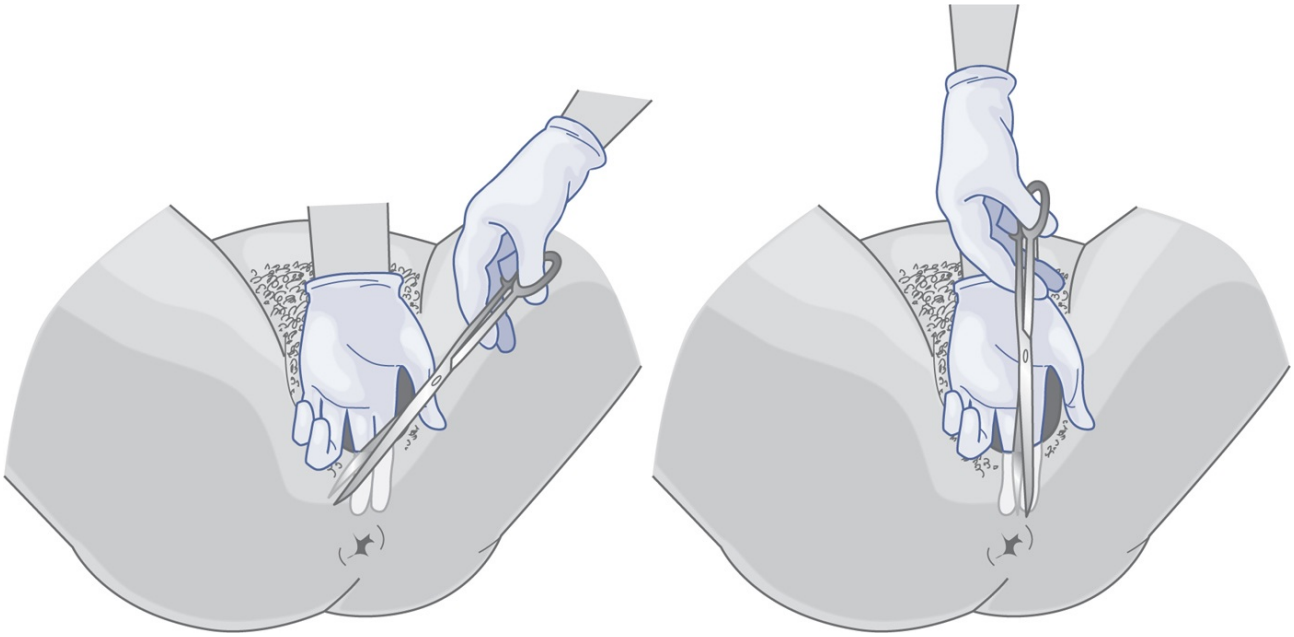

Figure 28F-15 Types of episiotomies.

The primary advantage of a mediolateral episiotomy is that fewer extensions into a third- or fourth-degree laceration occur, as compared to the outcomes of midline episiotomies. Some studies have found mediolateral episiotomies to be associated with more blood loss; others have not. Compared to midline episiotomies, mediolateral episiotomies can be more challenging to repair. The superior side of the wound has a larger area of exposed tissue than the inferior side, requiring larger "bites" of tissue superiorly when stitching.

When to Cut an Episiotomy

There is little evidence to guide a midwife regarding when to cut an episiotomy. Performing this procedure too early may result in extra blood loss. Waiting until the perineum is paper thin and the tissue bulging, however, may result in a rapid and perhaps uncontrolled birth of the fetal head, with resulting extension of the episiotomy. Many midwives advocate incision when the head is crowning and not retracting between contractions, such that birth is expected within a few contractions. When the head is well applied to the perineum, it also provides a type of tamponade to decrease bleeding.

After the episiotomy is performed, the midwife should continue to apply gentle pressure to the fetal head to control and direct a slow extension of the head. This will help avoid a rapid birth, sudden pressure on the perineum, and extension of the incision. Pressure on the wound to control bleeding may also be required between maternal pushing efforts.

Technique for Performing an Episiotomy

1. The midwife places the index and middle fingers into the vagina, palmar side down and facing away from the woman. The fingers should be slightly separated and provide gentle outward pressure on the perineal body to create adequate space between the

perineum and the head, and to allow the scissors to slip between the fingers using them as a guide. Thus, the fetal head is not touched, yet protected. The pressure also slightly flattens the perineal area, providing an easier incision.

2. Place the blades of the scissors in the appropriate direction—either straight anterior–posterior or diagonally, depending on the type of episiotomy to be cut. One blade of the scissors should be against the posterior vaginal wall, while the other blade should be against the skin of the perineal body, with the point where the blades cross at the midline of the posterior fourchette.
3. Locate the external anal sphincter by palpation using fingers in the vagina and the thumb of the same hand placed externally to the perineal body. Knowing the location of the external anal sphincter minimizes hesitation in cutting an adequate episiotomy due to fear of accidentally cutting through the sphincter.
   a. When cutting a midline episiotomy, adjust the length of the blades of the scissors on the perineal body to the projected length of the incision and terminate above the anal sphincter.
   b. When cutting a mediolateral episiotomy, position the blades so that there is approximately 1 cm of levator ani muscle between the incision and the sphincter. Another way to visualize this is to cut laterally from the midline at a 40–60° angle.[15] This directs the incision far enough laterally to avoid the sphincter during the process of cutting the episiotomy and when performing the repair. Take care not to start the incision on the lateral aspect of the fourchette or to direct the incision too far laterally to avoid incising the Bartholin gland on that side.
4. Incise the perineum with a single cut that is sufficient to open the perineal body and extend into the vaginal vault. Incising in this manner opens the vagina and the perineum. Performing a single incision through both the vagina and the perineum with one cut avoids the need for multiple incisions and increased trauma to the tissue.
5. After the initial incision, observe and evaluate the area to identify any active bleeding. Adequate visualization usually requires use of sponges to blot away blood, although excessive and aggressive blotting or using the sponges to wipe can further harm the tissue.
6. If a second incision is necessary, it can be performed at this time. Extension of an incision is best made by using fingers in the vagina to guide the incision and protect the fetal head.
7. By palpating for a band of tight, restricting vaginal tissue just inside the introitus, the midwife can further evaluate the adequacy of the incision. If such a band is present, it can be determined whether the band must be cut to be released.

Introduction

Even under the most normal of circumstances, intrapartum complications can occur. While many of these situations develop gradually or are associated with an already known high-risk condition, some will arise suddenly and without warning. This chapter builds on material reviewed in the *Pregnancy-Related Conditions* and *Medical Complications in Pregnancy* chapters. An overview of selected complications and conditions that can occur during the intrapartum period is presented. Familiarity with intrapartum complications and emergencies is essential to midwifery practice and requires frequent review of current management guidelines. Additional resources and study may be necessary for a more thorough exploration of the underlying pathophysiology associated with certain preexisting high-risk conditions.

When intrapartum complications are encountered, initiation of interventions often follows a specific progression as the situation evolves. This requires the midwife to be vigilant for worsening signs or symptoms. In addition, the need for intervention may disrupt the normal process of labor and will necessitate a careful evaluation of the risk–benefit ratio of intervention versus nonintervention. Shared decision making with the woman and her support persons regarding changes in the plan of care is an important component of midwifery management and should be used if possible when a deviation from normal is encountered.[1]

If an obstetric emergency occurs during the intrapartum period, prompt recognition and action is required to avoid serious adverse maternal or fetal outcomes, and shared decision making may not be possible. The midwife must also be ready and able to manage acute emergent situations within the appropriate institutional and legal boundaries of midwifery practice until the complication is resolved or the consulting physician can take over.

In some cases, a collaborative management plan with the consulting physician will already be in place prior to the onset of labor. The development of a new intrapartum complication or deviation from normal labor progress will require the midwife to seek physician consultation or to establish a collaborative plan of care. Within this collaborative model of care, the midwife provides continuity of care and advocacy for the woman, and protects normal labor progress as the clinical situation allows. Additionally, the midwife contributes to medical decision making while promoting family-centered care and keeps the consulting physician informed of any changes in the woman's condition. The medical rationale for consultation, collaboration, and referral as well as the resultant personnel involved in a woman's care are always clearly documented in her health record.

In cases where referral of care is indicated, the midwife can maintain an active role in the supportive care of the woman and her family, seeking the most appropriate balance of medicine and midwifery in collaboration with the physician. This supportive role is ongoing throughout the woman's intrapartum clinical course and continues into the postpartum period as needed. Women who experience an unanticipated obstetric complication or emergency will greatly benefit from the continuity and emotional support provided by their midwife.

Preterm Labor/Birth

Preterm birth is one of the leading causes of neonatal mortality in the United States.[2] Infants born prior to 37 weeks' gestation also face an increased risk of morbidity, such as neurologic and developmental disabilities. The *Pregnancy-Related Conditions* chapter details risk assessment for preterm birth and the role of various prevention strategies. In this chapter, the focus is on the evaluation and management of women who have suspected or confirmed active preterm labor.

Evaluation of Women with Possible Preterm Labor

Anticipatory guidance about signs and symptoms of possible preterm labor (PTL) should be provided during prenatal care, and women should be encouraged to report any such signs or symptoms. Women who are experiencing painful or frequent uterine contractions or more than 6 contractions per hour, vaginal bleeding, or any loss of fluid prior to 37 weeks' gestation should be evaluated promptly for possible preterm labor.[3] Other less-specific symptoms, such as cramping, pelvic pressure, abdominal pain, back pain, and watery vaginal discharge, could also indicate preterm labor.

The differential diagnoses for spontaneous PTL includes physiologic causes such as Braxton Hicks contractions, dehydration, lax vaginal tone, and round ligament pain. Other, more serious etiologies, such as infection (intrauterine, renal, genital tract), abruption, trauma, or appendicitis, must be considered as well and assessed for when obtaining a history and conducting a physical examination. The evaluation procedure for preterm labor is outlined in **Table 29-1**.

Table 29-1	Evaluation for Preterm Labor

1. History and Chart Review

a. Confirm the gestational age using the most credible data available.
b. Review the woman's history for any preterm birth risk factors, especially for prior spontaneous preterm births or unexplained second-trimester loss.
c. If there is a history of prior preterm birth:
    i. Has the woman been receiving 17-hydroxy-progesterone injections?
    ii. Are serial cervical length measurements obtained via ultrasound or other cervical measurement instrument documented on prenatal record ?
d. Inquire about recent intercourse, strenuous physical activity, abdominal trauma, vaginal bleeding, loss of fluid, fever, nausea, vomiting, urinary tract infection symptoms, or abnormal vaginal discharge.

2. Physical Examination

a. Note the woman's demeanor, distress, and/or coping.
b. Assess temperature, pulse, respirations, and blood pressure.

c. Palpate the lower back and assess for CVAT tenderness to rule out independent or concomitant UTI.
d. Palpate the abdomen for rebound tenderness; note any guarding.
e. Palpate the uterus for fundal tenderness, contraction strength, and fetal position (Leopold's maneuvers).
f. Place the woman on continuous electronic fetal monitoring to assess fetal well-being and uterine activity.
g. Perform a sterile speculum examination:
    i. If there is pooling fluid, check nitrazine, check for ferning, or use other assessment method to rule out PPROM.
    ii. If there is no history of bleeding, vaginal examinations, or intercourse in the past 24 hours, obtain an fFN culture (see **Figure 29-1** for collection technique).
    iii. Obtain cultures for gonorrhea and chlamydia.
    iv. Obtain a specimen for wet mount to assess for bacterial vaginosis or trichomoniasis infection.
    v. Obtain a sample from the proximal third of the vagina and through the rectal sphincter for GBS culture.
h. If there is no evidence of PPROM, perform a digital cervical examination to assess dilatation, effacement, station, and presenting part.
i. Laboratory tests:
    i. Clean catch urinalysis (with microscopic analysis) and urine culture
    ii. Complete blood count
    iii. Other labs as clinically indicated
j. Ultrasonography
    i. Perform transvaginal assessment of cervical length (depending on institutional protocols and availability).
    ii. If ultrasound is performed, confirm the presenting part.

Abbreviations: CVAT, costovertebral angle tenderness; fFN, fetal fibronectin; GBS, group B *Streptococcus*; PPROM, premature prelabor rupture of membranes; UTI, urinary tract infection.

Fetal Fibronectin

Contraction frequency is a poor predictor of subsequent preterm birth. When evaluating women for possible preterm labor, diagnostic accuracy may be improved with use of fetal fibronectin and measurement of cervical length by vaginal ultrasound.[3]

When evaluating women for possible preterm labor, diagnostic accuracy may be improved with use of fetal fibronectin and measurement of cervical length by vaginal ultrasound.[4-6] *Fetal fibronectin* (fFN) is a biochemical marker that may aid in management of women with symptoms of preterm labor. This extracellular glycoprotein, which is found in the amniochorionic membrane, serves as an adhesive binder between the membranes and the decidua. It is normally present in cervicovaginal secretions prior to 20 weeks' gestation and again after 37 weeks' gestation as cervical remodeling takes place in preparation for normal full-term labor. Between 24 and 34 weeks, the presence of fFN is atypical and could indicate inflammation or uterine activity—both of which are precursors to preterm birth.[4]

Unfortunately, studies have found that fFN has a poor positive predictive value (PPV). The reported PPV among women who present with preterm labor symptoms varies from 13.9% to 25.9%.[5,6] Conversely, fFN has a high negative predictability (97.6%) for indicating that birth will not occur within 7 days.[6] In practical terms, this means that fFN should not be used as a screening test.[6] A positive fFN test in symptomatic women has limited clinical utility and

should not be used alone to determine management. However, a negative fFN test can be helpful in avoiding unnecessary treatment in symptomatic women, especially in equivocal situations such as a woman with contractions and no cervical change. Women with symptoms of preterm labor between 24 and 34 weeks' gestation with a negative fFN culture (or assay) have only a 1% to 2% chance of giving birth within the next 7 to 14 days.[6]

Fetal fibronectin is tested by sampling vaginal secretions; this sample must be collected prior to any other vaginal examinations. fFN sampling is contraindicated if there is evidence of ruptured membranes. The accuracy of fFN testing is decreased in the presence of lubricants, blood, recent intercourse, or cervical manipulation within the previous 24 hours. A sample of vaginal secretions should not be collected for fFN testing in these situations or if the cervix is more than 3 cm dilated or 80% effaced.

Typically, the fFN sample is collected at the beginning of the examination of a woman presenting with preterm labor symptoms and set aside until the results of a digital cervical examination and possibly a transvaginal ultrasound cervical length measurement are available. The culture can then be sent or discarded depending on the clinical situation. The fFN collection technique is outlined in **Figure 29-1**.

Cervical Length Measurement

As discussed in the *Pregnancy-Related Conditions* chapter, transvaginal ultrasound cervical length measurement can be used as a screening tool for asymptomatic women. A cervical length of 25 mm or less after 16 weeks' gestation and before 24 weeks' gestation is associated with an increased risk of preterm birth.[7] In women who are more than 24 weeks' gestation, cervical length assessment can be a helpful adjunct to fFN testing. Some researchers now advocate combining fFN and cervical length in standardized preterm labor algorithms.[4,8,9]

In these suggested protocols, women presenting with preterm labor symptoms between 24 and 34 weeks' gestation would have an fFN collected (if not contraindicated) during their initial speculum examination, followed by a cervical length measurement. The results of the

cervical length measurement determine whether the fFN test was needed. The fFN does not aid diagnosis if the cervical length is very short (< 20 mm) or very long (> 30 mm) and in those cases, the sample collected may be discarded. For example, a cervical length of 30 mm or more is considered normal and has a negative predictive value that preterm birth will not occur that is 96% to 100%.[8] The fFN culture could then be discarded and the woman discharged home pending any other clinical problems that need to be addressed. If the cervical length is between 20 and 29 mm, however, the fFN is sent for analysis. A negative fFN would again be reassuring and indicates preterm birth is unlikely. In contrast, a positive fFN in this situation or a cervical length of less than 20 mm would warrant admission and initiation of preterm labor treatment.

The cut-off value for cervical length varies between 20 mm and 30 mm. Because the positive predictive value of both fFN and cervical length measurements is inexact, management should nor rely on these measurements alone when a woman has acute symptoms. Although preterm labor evaluation algorithms appear to reduce false-positive diagnoses and decrease unnecessary hospital admissions, the availability of cervical length ultrasound is limited in many areas and its performance requires specialized training and credentialing.

It can be challenging to formulate a plan for women who have some symptoms of preterm labor but no cervical dilation. The March of Dimes has provided recommendations for this situation that may prevent unnecessary hospitalization or interventions.[3] If gestational age is less than 34 weeks, the March of Dimes recommends fFN and/or cervical length (CL) measurement by transvaginal ultrasound. If fFN or CL measurement is not done, or if the woman is at 34 gestational weeks or more, a repeat assessment of cervical dilation by digital cervical examination 2 hours after the initial assessment should be done, ideally by the same examiner. If the fFN is negative or the CL measurement is 25 mm or more, or if there is no change in the cervix detected by digital cervical examination, the March of Dimes recommends the woman be discharged home.[3]

Treatment of Preterm Labor

For women in active preterm labor between 34 and 37 weeks' gestation, the midwife should consult with a physician regarding a collaborative management plan, depending on individual practice guidelines and institutional resources. If the woman is less than 34 weeks' gestation and her initial cervical examination is more than 3 cm dilated or 80% effaced, preterm labor treatment should be initiated and the woman referred for immediate medical management. Many smaller institutions will transfer women in preterm labor at less than 36 weeks' gestation to a tertiary center, because tertiary centers have specialized neonatal care available. Midwives in all practice settings should be aware of the current preterm labor treatment recommendations and initiate these interventions as the clinical situation requires. Any other abnormalities encountered by the midwife during the initial data collection should be managed and treated according to individual practice guidelines.

In the past, strategies such as bedrest, home contraction monitoring, maintenance tocolysis, hydration, periodontal care, and abstinence from intercourse were used to prevent preterm labor and birth. Evidence has not found these methods to be effective in reducing the preterm

birth rate; thus, they are no longer used as specific preventive or treatment therapies.[9]

There is also extensive evidence regarding the use of tocolytic medications to prolong pregnancy. Several different agents have been studied over the past 50 years, but none has effectively reduced the preterm birth rate or decreased neonatal mortality and morbidity (**Table 29-2**).[9,10] It is important to remember that tocolysis is contraindicated if the woman has any condition that requires labor such as intrauterine fetal demise, nonreassuring fetal status, severe preeclampsia, chorioamnionitis, lethal fetal anomaly, maternal bleeding with hemodynamic instability, or any maternal contraindication to use one of the tocolytic agents.[9]

Table 29-2 Tocolytic Medications Used to Treat Preterm Labor

Mechanism of Action	Dose	Common Maternal Side Effects	Fetal Effects	Contraindications/Cautions
Nifedipine (Procardia)				
Calcium channel blocker that directly blocks calcium ion influx through cell membrane and release of intracellular calcium from sarcoplasmic reticulum. This inhibits myometrial contraction	Optimal dose has not been established Common regimen is loading dose of 20–30 mg orally given in divided doses Then 10–20 mg orally every 3–8 hours	Peripheral vasodilator, may induce transient nausea, flushing, headache, palpitations, hypotension, dizziness, tachycardia	Secondary to maternal hypotension	Contraindications: Preload-dependent cardiac disorder, left ventricular dysfunction, congestive heart failure or hemodynamic instability Do not use concurrently with terbutaline or magnesium sulfate
Indomethacin (Indocin)				
Cyclooxygenase (COX) inhibitor reduces prostaglandin production by COX	Loading dose: 50–100 mg orally or 50 mg rectally Then 25–50 mg orally every 6 hours, for 48 hours	Gastrointestinal: nausea, vomiting, reflux, gastritis Platelet dysfunction	Premature closure of ductus arteriosus Oligohydramnios	Contraindicated for women with platelet dysfunction, bleeding diathesis, hepatic dysfunction, gastrointestinal ulcerative disease, and asthma if sensitive to aspirin Not recommended for more than 48 hours of continuous use Not recommended for women at ≥ 32 weeks' gestation
Magnesium sulfate				
Mechanism of action unknown but probably competes with calcium at cell membrane which reduces calcium available for myometrial contraction	Loading dose: 4–6 g intravenously (IV) over 20–30 minutes Then 2 g/hour by continuous IV infusion (pump required)	Flushing, nausea, blurred vision, headache, lethargy, muscle weakness, hypotension Rare effects: pulmonary edema, respiratory or cardiac arrest	Neuroprotective, Decreased fetal heart rate variability Decreased neonatal tone	Contraindicated for women with impaired renal function, myasthenia gravis, cardiac conduction defects Do not use concurrently with nifedipine Toxicity: loss of patellar reflexes, decreased urine output < 30 mL/hr, respiratory rate < 12/min Toxicity risks increase with serum creatinine > 1.0 mg/dL
Terbutaline (Brethine)				
Beta-agonist binds to beta-2 adrenergic receptors that cause a chain reaction resulting in depletion of intracellular calcium thereby blocking myometrial receptors. Receptors can become desensitized with prolonged use thereby diminishing effectiveness.	Varying doses used Common regimen is 0.25 mg subcutaneous (SQ) injection every 20 to 30 minutes up to 4 doses Then 0.25 mg SQ every 3-4 hrs. May be administered by continuous intravenous infusion	Tachycardia, peripheral vasodilation, hypotension, bronchial relaxation, pulmonary edema, hyperglycemia, myocardial infarction.	Tachycardia, neonatal hypoglycemia	Contraindications: tachycardia sensitive cardiac disease, poorly controlled hypertension, poorly controlled diabetes. Use with caution in women with hemorrhage as tachycardia and hypotension can complicate symptoms of hemorrhage The FDA has a black box warning that terbutaline should not be used for tocolysis for more than 72 hours secondary to the risk for maternal cardiac problems and recommends against use of oral terbutaline secondary to lack of proven effectiveness. However ACOG states terbutaline can be used for short term inpatient use

Tocolytics

All tocolytic agents slow uterine contractions to some degree, but at best they will delay birth for only 2 to 7 days.[9,10] In the past, magnesium sulfate and beta-mimetics (terbutaline [Brethine]) were the most commonly used tocolytic medications. More recently, research has shown that calcium-channel blockers (nifedipine [Procardia]) and prostaglandin synthetase inhibitors (indomethacin [Indocin]) have the best clinical efficacy and a lower incidence of

toxicity and maternal side effects when compared to magnesium sulfate and terbutaline.[9] As a result, terbutaline is no longer recommended for acute tocolysis, and magnesium sulfate should be reserved for clinical situations in which nifedipine and indomethacin are contraindicated or fetal/newborn neuroprotection is sought.[9]

Regardless of the agent chosen for tocolysis, the primary goal is to delay birth long enough to administer a full course of corticosteroids to facilitate fetal lung development and arrange for transfer of the woman to a tertiary center if needed. These two interventions have demonstrated dramatic improvements in neonatal outcomes and are the mainstay of preterm labor management.

Corticosteroids for Fetal Lung Maturity

The administration of corticosteroids to women in preterm labor between 24 and 34 weeks' gestation has been conclusively shown to improve fetal lung maturity and decrease other morbidities associated with prematurity.[9] Either betamethasone (Celestone) 12 mg intramuscularly (IM) given in two doses 24 hours apart or dexamethasone (Decadron) 6 mg IM given in four doses 12 hours apart can be used.[9] Once the woman has received a complete course of steroids, tocolysis is discontinued. If she does not give birth, the full steroid course can be repeated once as a "rescue dose" if more than 2 weeks has passed, the gestational age is less than 33 weeks, and the woman has a risk of birth within 7 days.[9] Some evidence suggests that a "rescue dose" may also be beneficial when the time period since the last course of steroids is 7–14 days.[9] Newer research suggests that administration of steroids in the late preterm period may also be beneficial.[11] Therefore, in women with a gestational age of 34 0/7 to 36 6/7 weeks at risk of preterm birth within 7 days who have not yet received steroids, this treatment should be considered.[9]

Group B Streptococcus Prophylaxis

Another important intervention in the treatment of preterm labor is the administration of antibiotics to prevent group B *Streptococcus* (GBS) disease. Preterm infants are especially susceptible to GBS sepsis, and the woman experiencing preterm labor will likely have unknown colonization status because the standard screening culture is not performed until 35 to 36 weeks' gestation. All women in preterm labor prior to 37 weeks with unknown GBS status should receive antibiotic prophylaxis.[12] The Centers for Disease Control and Prevention (CDC) website maintains updated GBS treatment guidelines and algorithms for GBS prevention strategies.[12]

Magnesium Sulfate for Neuroprotection

In addition to having some tocolytic properties, magnesium sulfate reduces the risk of cerebral palsy in infants born prior to 32 weeks' gestation.[9] Many institutions now include administration of magnesium sulfate as part of preterm labor management. Although the exact mechanisms of fetal neuroprotection are unknown, it is hypothesized that the magnesium sulfate

improves fetal cerebral blood flow and safeguards the fetus against hypoxic stress. Given that prematurity and low birth weight are the most significant risk factors for cerebral palsy, fetal neuroprotection has the potential to greatly improve the neurodevelopmental future of children born prior to 32 weeks' gestation.

Institutions that use magnesium sulfate for fetal neuroprotection should establish written guidelines and dosing protocols for this therapy.[7] These guidelines should also include an informed consent process and shared decision-making discussion with the woman and her family regarding the risks and potential benefits of magnesium sulfate in preventing cerebral palsy. It is important for the midwife to be aware of these guidelines and to appreciate the distinction of using magnesium sulfate for this indication *separately* from tocolysis. More importantly, the full dosing protocol for neuroprophylaxis differs from the magnesium sulfate doses used in the past for tocolysis and the dosing regimen currently used for treatment of preeclampsia/eclampsia.

Follow-Up

Women admitted for treatment for preterm labor will typically remain in the hospital for at least 24 hours. Once the full course of steroids is completed, tocolysis is usually discontinued and expectant management is resumed if the woman has not given birth. Women with advanced cervical dilation may need prolonged inpatient care and monitoring, especially if they are at a periviable, extremely preterm, or very preterm gestational age. The midwife can maintain an active supportive role in the woman's care during hospitalization and discuss the continued management plan with the physician as the clinical scenario changes. Prior to the woman's discharge from the hospital, the midwife may be involved in reassessment for preterm birth risk factors and initiation of any necessary treatments or interventions.

Outpatient monitoring will include weekly prenatal visits for the remainder for the pregnancy with either the midwife or the physician, or both, according to the plan of care. The woman should also be counseled about any signs of preterm labor and advised to call if any symptoms are noted. If symptoms do occur, the woman should be reassessed promptly in the hospital and the appropriate treatments repeated if needed.

Post-Term and Late Term Pregnancy

Concerns over the increased risks associated with giving birth during late term and post-term gestational weeks, particularly perinatal mortality, have prompted investigation of interventions to improve outcomes. The primary intervention studied has been induction of labor. Research has sought to determine whether routine induction improves outcomes and at which gestational age, and to identify any associated risks, especially an increased rate of cesarean births.

Expectant Management Versus Induction of Labor

Three meta-analyses comparing routine induction and expectant management for late term and post-term pregnancy have been conducted and produced slightly different results.[13-15] The authors of a 2012 Cochrane Review concluded that routine induction at 41 weeks results in a lower perinatal mortality rate (0.03% or 1/3285 birth vs. 0.33% or 11/3238 births, respectively) without an increase in cesarean births.[13] In the meta-analysis by Wennerholm et al., the authors found a lower incidence of cesarean birth and meconium aspiration syndrome with induction of labor at 41 weeks as compared to expectant management, and no difference in the perinatal mortality rate with the two management options.[14] Sanchez-Ramos et al. reported a lower rate of cesarean births and perinatal mortality with induction at 41 weeks as compared to expectant management, although the difference in the rates of perinatal mortality did not reach statistical significance.[15]

The risk of cesarean birth associated with induction of labor for late term or post-term gestation must be considered separately from the risk of cesarean associated with routine induction at any gestational age. The latter is discussed in the “Induction of Labor” section in this chapter. The evidence is clear that induction of labor for later term and post-term pregnancy does not increase the risk of cesarean, and may actually lower the incidence of cesarean birth.[13-15]

Based in this evidence, the American College of Obstetricians and Gynecologists (ACOG) supports considering induction between 41 0/7 and 41 6/7 weeks. Induction of labor is recommended at 42 0/7 weeks and indicated for all women who reach 42 6/7 weeks’ gestation based on the consensus of evidence that there is an increased risk of perinatal mortality and morbidity at that time.[16]

Expectant management of women with late term and post-term pregnancy includes antepartum fetal surveillance such as a nonstress test or a biophysical profile. Fetal surveillance has not been shown to decrease perinatal morbidity and mortality,[15] as studies in women who are post term have not included an unmonitored control group for ethical reasons. Regardless, starting antepartum fetal surveillance at 41 weeks’ gestation provides reassurance and is a commonly accepted practice.

Midwifery Management of Women at Post-Term Gestational Ages

When a pregnant woman approaches 41 0/7 weeks’ gestation, prenatal care must include a

discussion of management options for late term and post-term pregnancy. During this discussion, it is important to clearly separate the evidence on (1) the risks of late term and post-term pregnancy, and (2) the outcomes comparing induction of labor and expectant management with fetal surveillance as care options for late term and post-term pregnancy.

Principles of shared decision making can best guide the discussion which includes an explanation of the evidence showing increased risk after 41 weeks, and evidence on pros and cons of the different management options. These principles include the use of absolute risk as opposed to relative risk, and may include use of a visual aid such as a pictograph.[17] Relative risk versus absolute risk is important in this context. Perinatal mortality is a rare outcome, and the absolute risk of stillbirth and early neonatal death in uncomplicated pregnancies is small. The use of relative risk to explain this numeric evidence can introduce unintended bias.[17]

A discussion of the woman's values, goals, and preferences as they relate to the options for care is another principle of shared decision making and is a critical component of midwifery management of women with a late term and post-term pregnancy. Some women are anxious to end their pregnancies at the soonest possible time and will readily request induction of labor at 41 weeks. Some women find any increase in risk of perinatal mortality unacceptable and choose induction to mitigate this risk. Other women have a strong preference to avoid induction and may choose to await spontaneous labor.

If a woman declines induction at 42 0/7 weeks' gestation, consultation with a physician usually occurs for a continued plan of care. Careful fetal surveillance must be recommended, as well as ongoing discussion with the woman regarding the risks and benefits of induction versus awaiting spontaneous labor. Any consultation, results of fetal surveillance, and details of the discussion with the woman are documented in the health record.

Prelabor Rupture of Membranes

Prelabor rupture of membranes (PROM) is defined as rupture of the membranes prior to the onset of labor. This condition is also referred to as premature rupture of the membranes, although the use of the word "premature" may be confusing in this context because it is often used to refer to gestational age. When this event occurs in women who are less than 37 weeks' gestation, it is referred to as Premature prelabor rupture of membranes (PPROM). Prelabor rupture of the membranes at term gestation is a normal process associated with physiologic weakening of the amniotic membrane as labor nears. PPROM, in contrast, is thought to result from some type of underlying pathology, such as infection. The recommended management differs considerably for term and preterm PROM; thus, these conditions are considered separately here.

Evaluation for Ruptured Membranes

The diagnosis of PROM is clinical and based on evaluation of fluid present in the vagina. A history of a sudden gush of fluid that soaks underwear is a strong indication that PROM has occurred. Some women will report "feeling wet" or an intermittent gush of a small amount of fluid; in these cases, the diagnosis can be more difficult to make. Evaluation of the woman with possible ruptured membranes is reviewed in the *First Stage of Labor* chapter.

Premature Prelabor Rupture of Membranes

Management of PPROM and PROM at term can be either expectant or treated with induction of labor. In general, the fetus will benefit from a longer period in utero unless other complications are present. Unlike in women with term PROM, subclinical or clinical infection is often present in women who present with PPROM. A substantial number of women with preterm PROM have clinically diagnosed infection; 15% to 20% have chorioamnionitis and 15% to 20% have postpartum endometritis.[17]

The management of PPROM is based on weighing the risks of prematurity against the risks of infection with prolonged latency and delayed delivery. In general, the latency period with PPROM lasts an average of approximately 1 week with expectant management, but in some cases, it may last several weeks. Pregnant women with confirmed PPROM should be referred to a consulting physician for the continued plan of care. The management decision at the time of diagnosis is based on gestational age, presence of other complications such as infection or preterm labor, fetal well-being, fetal lung maturity, and access to a neonatal intensive care unit.

PPROM at Less Than 23 Weeks

In situations where PPROM occurs prior to 23 weeks' gestation, an individualized collaborative approach that includes the neonatal team is necessary to best determine the course of treatment. GBS prophylaxis, tocolysis, corticosteroids, and magnesium sulfate for fetal neuroprotection are not recommended if the fetus is at a previable gestational age.[18] Extensive counseling and shared decision making with the woman and her family should occur.

The midwife can fill a valuable role by listening and helping the woman understand all the complex information she will be given in this situation.

PPROM at 23 to 33 6/7 Weeks

In gestations between 23 and 33 6/7 weeks, expectant management is preferred if there are no clinical signs of infection, fetal compromise, or labor. Transfer of the woman to a tertiary center should be arranged if necessary. In addition, a single course of corticosteroids is administered to improve fetal lung maturity, and antibiotics are administered to the woman to prolong the latency period. The regimen for latency antibiotics varies among institutions but always includes an antibiotic that is appropriate for GBS prophylaxis.[12] The CDC guidelines for GBS prophylaxis, which can be found on the CDC website, detail evaluation and management of women with PPROM with regard to culturing for GBS, time period over which to administer antibiotics, and management if the woman does or does not go into labor. ACOG recommends against the use of tocolytics in this situation. Magnesium sulfate for fetal neuroprotection is controversial but should be considered if the gestational age is less than 32 0/7 weeks and birth is thought to be imminent within the next 12 to 24 hours. Digital cervical examinations are contraindicated, so as to reduce the risk of chorioamnionitis. A baseline cervical examination should not be performed.

PPROM After 34 Weeks

The gestational age at which infection risk outweighs the risks associated with prematurity is not clear. ACOG recommends induction of labor for all women with PPROM at 34 weeks' gestation or greater.[18] Administration of betamethasone to reduce respiratory morbidity in the newborn is now recommended between 34 0/7 and 36 6/7 weeks' gestation, including when PPROM occurs.[18] A collaborative management plan can be considered between the midwife and the physician in these situations, and will also depend on institutional and individual practice guidelines for midwifery management of women in preterm labor.

The Term PROM Controversy

The primary risk associated with term PROM is development of infection, which is termed either intra-amniotic infection or chorioamnionitis. Factors most strongly associated with an increased risk of infection are digital cervical examinations, maternal colonization with GBS, duration of rupture, duration of labor, and duration of latency period (i.e., the time between rupture of membranes and onset of labor).[19]

The two management options for women with term PROM are induction of labor and expectant management. Primary questions of concern are which management option results in lower infection rates, and whether one of these options is associated with more cesarean births. The 1996 TermPROM study is the most relevant contemporary study due to its randomized design and large sample size.[20] In this study, neonatal infection rates and cesarean birth rates were similar in women who underwent induction and those managed expectantly,

but there was a higher rate of maternal infection in those women in the expectant management group. Several study limitations likely affected the risk of maternal infection in the expectant management group including an atypical diagnosis of chorioamnionitis, more digital cervical examinations in the expectant management group, and no prenatal GBS screening and therefore no antibiotic prophylaxis during labor for GBS-positive women.[21]

ACOG recommends induction of labor as the optimal management approach, but recognizes expectant management as an acceptable option for women who decline induction.[22] The American College of Nurse-Midwives' (ACNM) Position Statement on Premature Rupture of Membranes at Term reaffirms the woman's rights to self-determination and supports the option of expected management for low-risk women.[23] **Table 29-3** summarizes these recommendations.

Table 29-3 Criteria for Expectant Management of Prelabor Rupture of Membranes

Full term (> 37 0/7 weeks)
Singleton pregnancy
Vertex presentation
Clear amniotic fluid
No fever
No infection including HIV; hepatitis B and C
Not a known group B *Streptococcus* carrier (GBS negative)
No evidence of risk for fetal acidemia in fetal heart rate pattern
No health or obstetric condition that requires immediate induction of labor

Based on American College of Nurse-Midwives position statement: premature rupture of membranes at term. ACNM Division of Standards and Practice, Clinical Practice Section 2008; reviewed 2012. Available at: http://www.midwife.org/ACNM/files/ACNMLibraryData/UPLOADFILENAME/000000000233/PROM%20Mar%202012.p

Women who choose or require induction of labor should be admitted and a plan of care made, including decisions regarding cervical ripening and/or oxytocin infusion. Physician consultation may be indicated depending on institutional guidelines and the individual clinical scenario. If induction is chosen, it is important to allow adequate time for the latent phase of labor to avoid cesarean birth for failed induction. Multiple cervical examinations are a primary risk factor for infection, so digital cervical examinations should be minimized during induction.[18,19]

If expectant management is chosen, the management plan should include where the woman will await onset of labor and for how long, and how maternal and fetal well-being will be monitored during this time. There is little evidence on which to base the decision of where the woman should remain until labor starts,[17] and having her return home for a predetermined time may be considered. A woman who returns home for expectant management should be advised to monitor her temperature (with a thermometer) every 2 to 4 hours as well as contraction frequency and fetal movement. It is important to also counsel the woman to avoid inserting anything into her vagina. The woman should be advised to call immediately if she has a temperature of 38°C or higher, decreased fetal movement, signs of active labor, and either

meconium-stained or foul-smelling amniotic fluid. Plans for follow-up evaluation should also be made.

In the TermPROM study, the median latency duration was 33 hours and 95% give birth within 95–107 hours after rupture.[20] The optimal maximum duration of expectant management is not known. The TermPROM study allowed up to 96 hours before induction was performed.[20] Women choosing expectant management may elect to have their labor induced at any time.

Women with ruptured membranes must be monitored for developing infection regardless of the management option chosen. Fetal or maternal tachycardia, fever, uterine tenderness, and foul-smelling fluid are all signs of possible chorioamnionitis. Any of these signs or symptoms requires admission, physician consultation, and prompt initiation of the appropriate treatment interventions. To avoid infection, digital cervical examinations should be minimized during induced or spontaneous labor.[18,19]

Intrauterine Infection

Intrauterine infection or inflammation refers to infection of the amniotic sac, the amnion, and the chorion.[24,25] *Chorioamnionitis* is the historical term, but refers to a heterogeneous set of conditions characterized by infection and/or inflammation, which have differing degrees of severity. Therefore, the terms *intrauterine infection*, *intrauterine inflammation*, or *intrauterine infection and inflammation* (Triple I) have been proposed as replacements. The term *intra-amniotic infection*, which has also been proposed as a replacement for chorioamnionitis, is used in this chapter.

A common cause of intra-amniotic infection is ascending bacteria from the woman's lower genital tract. Organisms such as group B *Streptococcus*, *Escherichia coli*, *Ureaplasma urealyticum*, *Fusobacterium* species, and *Mycoplasma hominis* have all been implicated as causative pathogens.[26] Because the amniotic membrane provides some protection against fetal infection, prolonged rupture of membranes and long labor are risk factors for intra-amniotic infection. Manipulative vaginal or intrauterine procedures and frequent digital cervical examinations are also associated with an increased risk of intra-amniotic infection, especially once the membranes have ruptured.[24] Many of these factors are interrelated and, therefore, their independent effects have not been fully established. For example, an increased number of cervical examinations during labor is associated with longer labors and longer duration of membrane rupture, both of which are also associated with an increased risk of infection.[24,27]

The definitive diagnosis of intra-amniotic infection can be made only after the birth through histological examination of the placenta and membranes.[24,25] Maternal fever during labor is the primary clinical marker of intra-amniotic infection and is associated with 95% of cases.[26] However, fever can also be caused by maternal dehydration, overheated room temperature, and possibly prolonged time in the shower or tub. Furthermore, maternal fever is associated with epidural analgesia. Given these ambiguities, a National Institutes of Health Expert Panel Workshop held in 2015 evaluated the research on intra-amniotic infection and released new guidelines for diagnosis and management of this condition (**Table 29-4**).[25]

Table 29-4 Diagnostic Criteria for Intrauterine Infection, Intrauterine Inflammation, or Both

Diagnosis	Diagnostic Criteria
Isolated maternal fever	Oral temperature of 38–38.9°C that persists when the temperature measurement is repeated after 30 minutes
Suspected intrauterine infection, inflammation, or both (Triple I, intra-amniotic infection)	Oral maternal temperature of ≥ 39°C[a] without other symptoms *or* Maternal intrapartum fever and one or more of the following: Fetal tachycardia: FHR > 160 bpm Maternal leukocytosis: WBC count > 15,000/mm^3 if corticosteroids are not given Purulent discharge from the cervical os
Confirmed intra-amniotic infection	All of the above plus: Amniocentesis-proven infection via positive Gram stain and

	low glucose or positive amniotic fluid culture
	Placental histopathology with diagnostic features of infection

Abbreviations: FHR, fetal heart rate; WBC, white blood count.

[a] The National Institutes of Health Expert Panel identified an oral temperature of 39°C or greater without other symptoms as being an isolated maternal fever, but the American College of Obstetricians and Gynecologists included this finding as part of the criteria for suspected intra-amniotic infection.

Based on American College of Obstetricians and Gynecologists. Committee Opinion No. 712: intrapartum management of intraamniotic infection. *Obstet Gynecol.* 2017;130:e95-e101[24]; Higgins RD, Saade G, Polin RA, et al. Evaluation and management of women and newborns with a maternal diagnosis of chorioamnionitis. *Obstet Gynecol.* 2016;127:426-436.[25]

These definitions distinguish between suspected versus confirmed intra-amniotic infection and provide standardized temperature criteria for isolated maternal fever. The Expert Panel workshop criteria included women with temperature 39°C or greater but no other clinical risk factors in the isolated maternal fever group, whereas ACOG recommends that these women be treated as though they have suspected intra-amniotic infection.[24]

Some risk factors for intra-amniotic infection are modifiable. Thus, preventive measures such as promoting hydration during labor and avoiding digital cervical examinations are important components of midwifery practice. If the maternal temperature begins to rise, an intravenous fluid bolus can be given initially and the temperature rechecked in an hour.

Women with isolated maternal fever or suspected intra-amniotic infection are offered antibiotics in labor, and physician consultation or notification is indicated as well. Although no randomized trials have compared the various antibiotic regimens, broad-spectrum antibiotics such as ampicillin or penicillin, used in combination with gentamicin (Garamycin), are the most commonly recommended treatment for suspected infection. Administered intravenously until the woman gives birth, these antibiotics have consistently demonstrated the highest efficacy against the two leading causes of neonatal sepsis—namely, group B *Streptococcus* and *E. coli*. **Figure 29-2** shows the recommended dosing regimens, including alternatives for women with penicillin or ampicillin allergy.[24–26,28]

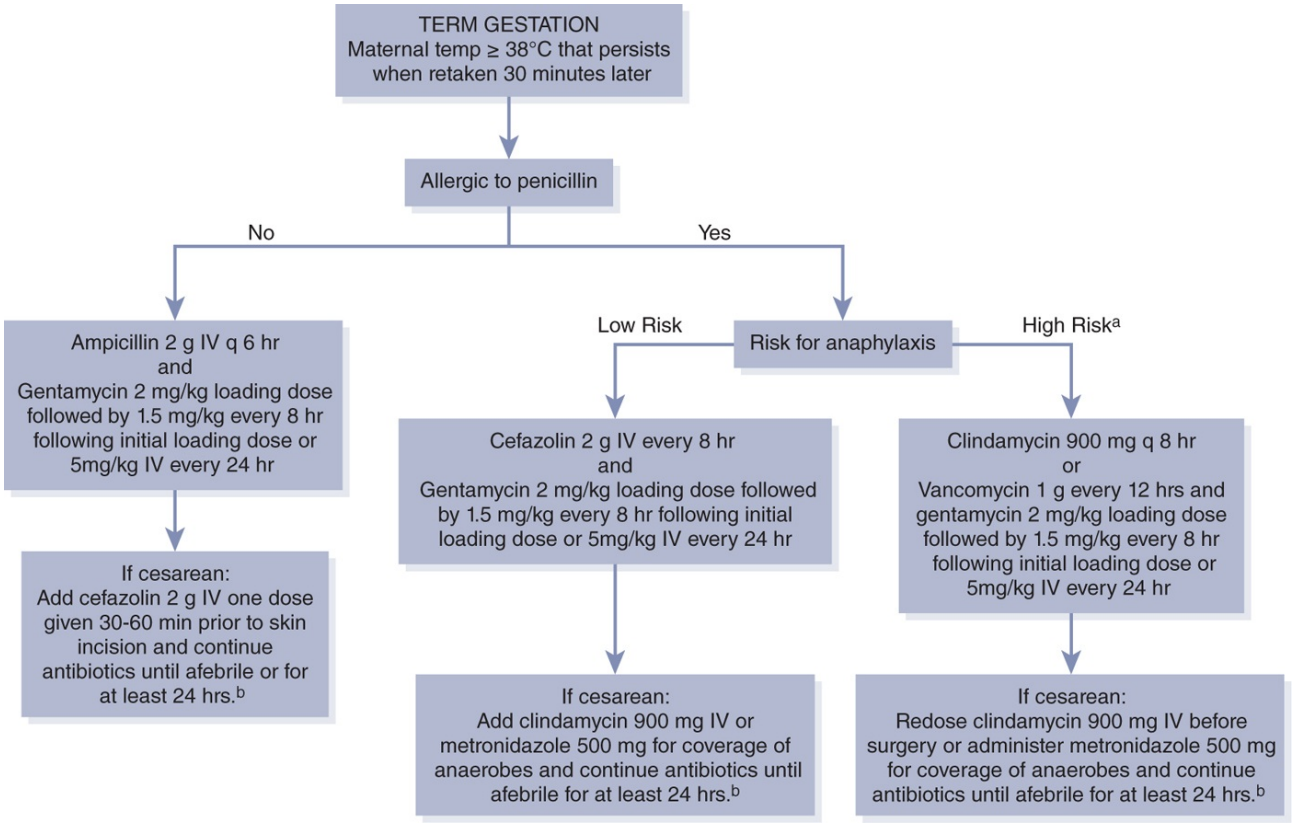

Figure 29-2 Treatments for isolated maternal fever and suspected intra-amniotic infection.

Abbreviations: g, gram; hr, hour; IV, intravenous; mg, milligram; min, minutes; q, every.

[a] High risk for anaphylaxis includes history of angioedema, respiratory distress, anaphylaxis, or urticaria (hives) after exposure to penicillin.

[b] Some authors suggest one dose following birth is sufficient. Thus, the duration of antibiotic administration after birth is based on institutional guidelines.

Based on American College of Obstetricians and Gynecologists. Committee Opinion No. 712: intrapartum management of intraamniotic infection. *Obstet Gynecol.* 2017;130:e95-e101[24]; Higgins RD, Saade G, Polin RA, et al. Evaluation and management of women and newborns with a maternal diagnosis of chorioamnionitis. *Obstet Gynecol.* 2016;127:426-436[25]; Fahey JO. Clinical management of intra-amniotic infection and chorioamnionitis: a review of the literature. *J Midwifery Womens Health*. 2008;53:227-235[26]; Fishman SG, Gelber SE. Evidence for the clinical management of chorioamnionitis. *Semin Fetal Neonatal Med.* 2012;17:46-50.[28]

Women who are being given penicillin or ampicillin for GBS prophylaxis are not sufficiently treated for intra-amniotic infection. If a woman who is receiving penicillin for GBS prophylaxis develops a fever during labor, a broad-spectrum antibiotic that is effective against anaerobic bacteria must be initiated.

Oral acetaminophen (Tylenol) 975 mg should also be given. Reducing the woman's temperature has been shown to improve fetal acid–base balance.[26] The woman’s condition and labor progress should be monitored closely. Oxytocin should be used if labor is not progressing normally. Intra-amniotic infection is not an indication for cesarean birth. If a cesarean birth is performed, the woman may need additional anaerobic antibiotic coverage with either cefazolin (Ancef) or clindamycin to prevent postpartum endometritis. Once birth occurs, the placenta is sent to the pathology laboratory for histologic evaluation and the infant

closely monitored for any signs of sepsis or infection. Intravenous antibiotics are typically continued for at least one additional dose after the delivery, although many institutions will extend postpartum dosing until the woman has remained afebrile for at least 24 hours.[28]

Induction of Labor

Induction of labor refers to stimulation of uterine contractions through artificial means. Methods for inducing labor include both hormonal and nonhormonal approaches. The decision to induce labor involves assessing the risks associated with continuing the pregnancy versus the risks associated with labor induction for both the woman and the fetus. Induction of labor can be elective or medically indicated. Examples of evidence-based medical indications for an induction of labor include gestational hypertension, preeclampsia/eclampsia, fetal growth restriction, cholestasis of pregnancy, diabetes mellitus, fetal demise, intra-amniotic infection, oligohydramnios, and nonreassuring fetal status.[29] Other medical indications include prelabor rupture of membranes and post-term pregnancy. Induction of labor should occur only in a hospital and is contraindicated in any situation that precludes vaginal birth, such as placenta previa, vasa previa, transverse lie, umbilical cord prolapse, previous myomectomy entering the endometrial cavity, previous classical uterine incision, active genital herpes infection, or presence of a Category III fetal heart rate (FHR) tracing.[30]

Elective induction (i.e., no medical indication for induction) is controversial. Factors such as maternal or provider convenience, history of fast labors, maternal distance from the hospital, relief of physiologic pregnancy discomforts, avoidance of certain calendar dates or holidays, institutional staffing concerns, and patient satisfaction have all been cited as reasons for elective induction. Risks associated with induction of labor include uterine tachysystole, fetal intolerance of labor, postpartum uterine atony, and possibly an increased risk for cesarean section. Adverse outcomes include increased incidence of neonatal morbidity from iatrogenic prematurity if the estimated gestational age is incorrect and increased costs.[30]

The relationship between cesarean birth and induction of labor is complex. Induction for certain indications, such as late term and post-term pregnancy[13] and prelabor rupture of membranes at term,[21] is not associated with an increased risk of cesarean birth. In the early 2000s, a considerable body of evidence developed demonstrating that the risk of cesarean section is substantially increased with induction in nulliparous women, with most researchers finding the risk to be at least doubled.[30,31] These studies compared labor outcomes in women who were induced versus labor outcomes in women who experienced spontaneous labor at the same gestational age. Some researchers have noted that the proper comparison group for women who are induced is actually women at the same gestational age who are managed expectantly.[32] Several recent studies, including a systematic review that used this comparison group, demonstrated a decreased rate of cesarean births in women whose labors were induced when compared to women who were managed expectantly.[33-36] More recently, a small randomized controlled trial (RCT) found that induction was associated with a higher rate of cesarean section (30.5% vs 17.7%; relative risk [RR], 1.72; 95% confidence interval [CI], 0.96–3.06) in nulliparous women at 39 weeks' gestation whose cervix was not favorable.[37] Although this result was not statistically significant, it may be clinically significant and suggests further research is needed to better parse the individual clinical characteristics that may or may not increase the risk of cesarean section following induction of labor. It is likely that the relationship between induction and cesarean birth is affected by multiple factors, such

as nulliparity, obesity, lack of cervical ripening, gestational age, and labor management practices.[34]

A positive relationship between elective induction of labor and an increased rate of iatrogenic prematurity is clear, and the practice of elective induction prior to 39 weeks' gestation has come under close scrutiny as the adverse effects associated with late preterm birth have become clearer. Strict criteria for gestational age dating are now in place, and elective induction prior to 39 weeks' gestation is contraindicated.[29] Some institutions have adopted stringent guidelines for elective induction at term that also require a favorable Bishop's score, a signed consent form, and a preinduction checklist for providers.[38,39] The Bishop's score is a numeric assessment of four different characteristics of the cervix and fetal station; it is used to predict the success of induction.[40,41] The currently used version of the Bishop's score is shown in **Table 29-5**.[29,40,41] The ACNM Position Statement on Induction of Labor (2016) recommends against the practice of elective induction of labor; midwives in clinical practice will find valuable information in this document.[42]

Table 29-5 **The Modified Bishop Scoring System**

Point Value	0	1	2	3
Cervical position	Posterior	Midline	Anterior	
Cervical consistency	Firm	Medium	Soft	
Cervical length[a] (cm)	> 4	2–4	1–2	< 1
Cervical dilation (cm)	0	1–2	3–4	> 5
Fetal station[b]	–3	–2	–1/0	+1/+2

[a] The original cervical length categories were cervical effacement of 0–30%, 40–50%, 60–70%, and greater than 80%. Either the original percent effacement or centimeters of cervical length may be used.
[b] Station is based on a –3 to +3 range.

Based on Bishop EH. Pelvic scoring for elective induction. *Obstet Gynecol.* 1964;24:266-268[40]; Lange AP, Secher NJ, Westergaard JG, Skovgård I. Prelabor evaluation of inducibility. *Obstet Gynecol.* 1982;60(2):137-147[41]; American College of Obstetricians and Gynecologists. Practice Bulletin No. 107: induction of labor. *Obstet Gynecol.* 2009;114:386-397. [Reaffirmed 2016].[29]

Prior to the initiation of any cervical ripening or induction methods, the woman should be counseled about the medical indication for induction as well as the risks and benefits to her and her fetus that are associated with induction and expectant management. In addition, a collaborative management plan between the midwife and the consulting physician regarding the plan of care for cervical ripening and induction of labor is required. **Table 29-6** summarizes key midwifery considerations when caring for women who require an induction of labor and/or cervical ripening.

Table 29-6 **Clinical Considerations Prior to Induction of Labor and/or Cervical Ripening**

1. Physician consultation should occur prior to the initiation of cervical ripening or oxytocin induction. In some cases, a collaborative management plan is required.
2. The medical indications for induction should be discussed with the woman and her support person(s). The

risks and benefits of each proposed agent (or technique) should be thoroughly reviewed. The woman's preferences should be taken into consideration. This discussion should be documented in her health record.

3. The pre-induction (or cervical ripening) database should include the following information:
   a. Documentation of the gestational age and criteria used to establish the final estimated due date.
   b. Bishop's score.
   c. Indications for induction or cervical ripening.
   d. No contraindications for induction.
   e. Clinical pelvimetry.
   f. Confirmation of a cephalic presentation.
   g. Confirmation of Category I fetal heart rate pattern. Induction may proceed with oxytocin if a Category II fetal heart rate pattern is present, following consultation with a physician.
4. The physician should be notified if the woman declines a medically indicated induction of labor.
5. Caution should be exercised when prescribing or recommending alternative methods of cervical ripening or induction of labor not supported in the scientific literature.
6. During an induction, practices that encourage the normal process of labor (e.g., ambulation with telemetry, oral hydration) should be encouraged.
7. Water immersion in the shower or tub (with waterproof fetal telemetry monitoring) may be considered during induction of labor with oxytocin.

Cervical Ripening Techniques

As pregnancy approaches full term, the cervix gradually begins to soften, efface, and move anteriorly in the vaginal vault. This process, which is commonly referred to as "ripening," occurs as a result of normal remodeling of the collagen fibers and other glycoprotein connective tissues within the cervix. Cervical ripening occurs more readily in multiparous women, and the process may begin in the days to weeks before the onset of labor.

The degree of ripening can be quantified using the modified Bishop's score, which takes into consideration all of the factors associated with cervical remodeling (**Table 29-5**). This scoring system indicates whether the woman's cervix is "favorable" or "unfavorable" with regard to predicting the success of labor induction and is the best predictor of induction success known to date.

For example, women who have a modified Bishop's score higher than 8 are considered to have a favorable cervix and a high probability for vaginal birth with induction of labor.[29] By comparison, women with a Bishop's score of 6 or lower have an unfavorable cervix, such that cervical ripening may improve their labor induction success rates. Cervical ripening agents can advance the Bishop's score by acting directly on the glycoproteins within the cervix (hormonal) or through mechanical dilation of the cervix. Because cervical dilation is considered to be the component of the Bishop's score that is most predictive of induction success, mechanical methods are often used concurrently either with hormonal ripening or during oxytocin induction. No cervical ripening method should be employed before 40 weeks' gestation unless there is a medical indication for induction.

Foley Balloon Catheter

The most common method of mechanical dilation is use of a Foley balloon catheter, although hydroscopic vaginal dilators (laminaria) are still used in some locations. Using aseptic technique, a Foley catheter with a 30-cc balloon is inserted directly into the cervix and advanced beyond the internal os. The balloon is then inflated to the full 30 cc with sterile water or saline, and the end of the catheter taped to the woman's leg, applying mild tension. Insertion can be done with direct visualization of the cervix using a speculum or during a digital examination. The balloon falls out on its own when the cervix dilates to 3 cm, which typically occurs within 6 to 12 hours. The insertion procedure may cause some discomfort for the woman and lead to persistent lower abdominal cramping. Accidental rupture of the membranes or cervical bleeding can also occur. The risks, benefits, and expected side effects should be explained to the woman prior to the insertion of a balloon catheter and documented with a procedure note in the woman's medical record.

Prostaglandin Agents for Cervical Ripening

The two hormonal agents currently used for cervical ripening indications are prostaglandin E_2 (dinoprostone [Prepidil, Cervidil]) and the synthetic prostaglandin E_1 analogue (misoprostol [Cytotec]). The current preparations, dosing regimens, and clinical considerations for these agents are outlined in **Table 29-7**.[43-45] A considerable amount of research has compared hormonal agents alone or in combination with mechanical dilation. This body of evidence has conclusively demonstrated that cervical ripening prior to initiation of oxytocin shortens the time of induction onset to birth and may increase the vaginal birth rate. To date, no preferred strategy for cervical ripening has emerged.[43] Vaginal administration of misoprostol is the intervention most likely to result in birth within 24 hours but is associated with the highest incidence of tachysystole; by comparison, use of a Foley catheter for cervical ripening is associated with the lowest rate of tachysystole. Oral misoprostol has the lowest rate of cesarean birth.[44]

Table 29-7 **Hormonal Cervical Ripening Agents**[a]

Drug: Generic (Brand)	Dose and Route	Onset of Action (min)	Peak Plasma Level (min)	Duration of Action (hr)	Mean Time to Sustained Uterine Activity (min)	Clinical Considerations
Prostaglandin E_1						
Misoprostol (Cytotec)	25–50 mcg orally every 3–6 hours	12 ± 3	20–30	2	90	Contraindicated in women with a scarred uterus Inpatient only with continuous fetal heart rate monitoring Vaginal doses of 50 mcg are associated with higher incidence of uterine tachysystole and are not recommended Oxytocin may be started 4 hours after last dose
Misoprostol (Cytotec)	25 mcg every 3–6 hours posterior vaginal fornix	20.9 ± 5.3	60–80	4.5–5	106	
Prostaglandin E_2						
Dinoprostone (Prepidil)	0.5 mg in 2.5 mL syringe; endocervical gel	Rapid onset	60–120	Variable	127	Inpatient only with continuous fetal heart rate monitoring Left in place for up to 12 hours Remove insert if more than 5 contractions/10 minutes (tachysystole) Oxytocin may be started 30–60 minutes after removal
Dinoprostone (Cervidil)	10 mg 0.3 mg/hour vaginal	Rapid onset	Unknown	Variable	Unknown	May be repeated every 6 hours × 3 doses Can be used for outpatient ripening in selected women Monitor fetal heart rate for 1–2 hours after each dose Oxytocin may be started 6–12 hours after last dose

[a] Cervical ripening agents are contraindicated if there is an abnormal FHR tracing or more than 3 contractions in a 10-minute window.

Based on American College of Obstetricians and Gynecologists. Practice Bulletin No. 107: induction of labor. *Obstet Gynecol.* 2009;114:386-397. [Reaffirmed 2016][29]; Yount S, Lassiter N. The pharmacology of prostaglandins for induction of labor. *J Midwifery Womens Health.* 2013;58:133-144.[43]

Many variables—such as provider preference, availability, and institutional guidelines—will determine which agents or methods are used. All hormonal agents can cause excessive uterine activity (tachysystole) or induce labor, so assessment of fetal well-being is an important prerequisite before hormonal ripening is started. The midwife should monitor the woman's response to cervical ripening and remain vigilant for signs of tachysystole or fetal intolerance to uterine activity.

Misoprostol (Cytotec)

Misoprostol is available as a 100- or 200-microgram (mcg) tablet. This agent is approved by

the U.S. Food and Drug Administration (FDA) and marketed for managing the symptoms of peptic ulcer disease. The tablets are not formulated for vaginal use, and misoprostol is not FDA-approved for cervical ripening. Nevertheless, it is effective for cervical ripening and is commonly used on an off-label basis for this indication. Misoprostol is contraindicated for women who have had a prior cesarean section or uterine surgery.

Misoprostol may be administered either orally or vaginally. Due to the potential dosing inaccuracies from splitting up the tablets, the uterine response can be somewhat unpredictable and unreliable, especially with vaginal dosing. As a precaution, the dose is not usually administered if the woman experiences more than 3 contractions in a 10-minute period.

Terbutaline should always be readily available to treat tachysystole that is associated with abnormal or indeterminate FHR patterns. Interestingly, although caution is warranted, episodes of FHR decelerations that occur in response to misoprostol-induced tachysystole have not been associated with adverse neonatal outcomes in the studies that assessed the effectiveness of misoprostol for cervical ripening.

Induction of Labor Techniques

Membrane Sweeping

Membrane sweeping is a practice often performed in the outpatient setting for women at term who desire an intervention to speed the onset of labor. Membrane sweeping is not an induction agent per se, but has been shown to shorten the time interval to onset of labor. This procedure is reviewed in detail in the *Pregnancy-Related Conditions* chapter.

Amniotomy

Planned artificial rupture of the membranes (AROM) may be used as a method of labor induction either alone or concurrently with oxytocin. Studies have shown amniotomy to be more effective when the cervix is favorable, but individual response to amniotomy can be unpredictable and this technique can result in long intervals before the onset of regular uterine contractions.[29] There is a potential risk of infection from a prolonged labor if amniotomy is performed when the cervix is unfavorable. When amniotomy is combined with oxytocin, the induction-to-birth interval is decreased; however, the best timing for AROM has not been clearly established. In addition, once the membranes have been ruptured, the woman is committed to giving birth and no longer has the possibility of further cervical ripening or reverting to a period of expectant management if a trial of oxytocin fails to initiate labor. For women with cervical dilation of 4 cm or less, early amniotomy is not associated with adverse maternal or neonatal outcomes and may shorten labor by 2 hours or more.[45]

The primary risk associated with amniotomy is umbilical cord compression—or, more emergently, a prolapsed umbilical cord. Variable decelerations are commonly seen when the umbilical cord is compressed; the management of variable decelerations is discussed in the *Fetal Assessment During Labor* chapter. Umbilical cord prolapse is an obstetric emergency regardless of whether the membranes ruptured spontaneously or following amniotomy and is the primary reason why amniotomy should not be performed if the fetal head is not engaged in

the pelvis. See the “Obstetric Emergencies” section of this chapter for detailed management guidelines for a prolapsed umbilical cord.

Induction of Labor with Oxytocin (Pitocin)

Oxytocin is a small, nine-amino-acid peptide hormone produced in the hypothalamus and secreted from the posterior pituitary gland. This hormone is similar to vasopressin and has a direct antidiuretic effect on the kidney. Most importantly, oxytocin is a potent uterotonic agent that causes uterine contractions. Although pituitary secretion appears to be the primary source of oxytocin, this hormone is also synthesized and secreted by the placenta and fetus. Synthetic oxytocin, which is chemically identical to endogenous oxytocin, is one of the most commonly prescribed medications in midwifery practice today.

When this medication is used appropriately, the clinical benefits are undeniable, especially for treating postpartum hemorrhage. However, oxytocin is associated with adverse fetal and maternal outcomes and frequently implicated in obstetric litigation cases.[46] As a result, oxytocin is now considered a “high alert” medication, which mandates compliance with safety measures to reduce the increased risks of error that may result in maternal or neonatal morbidities. Some of the safeguards currently in place include standardized intravenous concentrations, mandatory use of an infusion pump, continuous FHR monitoring, and lower-dosing protocols.[46,47]

Oxytocin exerts its effect via agonist action on oxytocin receptors that are present in the uterine myometrium. These receptors become active or “upregulate” more than 100-fold during early labor. The uterotonic effect mediated by receptor function is theorized to be the reason for the marked interindividual variability in responses to this drug. The oxytocin receptors also downregulate or become desensitized following prolonged exposure to oxytocin, which may partially explain why women who are exposed to long-duration oxytocin therapy for labor induction are at increased risk for postpartum hemorrhage.[48,49]

The onset of action of synthetic oxytocin is 3 to 4 minutes, and the half-life is approximately 15 minutes. The uterine response reaches a steady state after 30 to 40 minutes.[49] The individual response to a particular dose is both variable and dose dependent: As the infusion rate increases, the frequency and intensity of contractions follow.

Oxytocin Dosing Regimens. The variability in the individual response to oxytocin requires that the medication be started at a small dose and titrated until the desired contraction response is met. Various dosing regimens have been proposed, including those based on the starting dose and on the frequency at which the dose is increased and the amount of increase. Regimens are generally referred to as “low dose” or “high dose,” but these terms are not well defined. Generally, the higher-dose regimens include a starting dose of 6 mU/min that is increased by 3–6 mU/min every 15–40 minutes. In contrast, the low-dose protocols are based on the pharmacokinetics of oxytocin and use a starting dose of 0.4–2 mU/minute, which is increased by 1–2 mU/minute every 40 minutes. High-dose regimens are associated with more uterine tachysystole, a shorter interval between starting oxytocin and adequate labor, and shorter duration of labor. The evidence regarding cesarean birth rates with high-dose versus

low-dose regimens has been inconsistent, although most studies have not found that high-dose protocols increase the cesarean rate.[49-51] The influence of provider behavior on cesarean rates with oxytocin augmentation is not known.

Despite a lack of standard protocols, the trend is to use low-dose regimens that call for waiting at least 30 to 40 minutes before increasing the dose, to allow for evaluation of the full effects of the prior dose. This time frame allows the oxytocin administered to reach a steady-state plasma concentration and reduces the chance of dysfunctional uterine activity or tachysystole. Moreover, during the first stage of labor, there may be a small baseline concentration of endogenous oxytocin in the woman's circulation, which may combine with the intravenous oxytocin infusion to produce a cumulative effect on uterine contractions.[45,49,52]

Side Effects and Adverse Effects of Oxytocin. Oxytocin is contraindicated for women who have contraindications to induction of labor. This agent has an antidiuretic effect, so it must be used with caution in women who need fluid restriction or who are at increased risk for pulmonary edema. Oxytocin can cause hypotension, tachycardia, and transient myocardial ischemia that results in EKG changes if given as a bolus dose.

The most commonly encountered side effect of oxytocin is uterine tachysystole. Tachysystole is defined as more than 5 contractions in 10 minutes averaged over a 30-minute window.[53] Due to the short half-life of oxytocin, decreasing or stopping an oxytocin infusion will rapidly slow the frequency of contractions. In many cases, uterine tachysystole does not result in obvious fetal compromise but still requires an oxytocin dose adjustment to allow for adequate fetal oxygenation in between contractions. Titration of the infusion is highly individualized, with some finesse required to find a balance between the desired effect and avoidance of uterine tachysystole. Women receiving oxytocin also require an assessment of maternal and fetal status every 15 minutes during the active phase of labor and every 5 minutes during second-stage labor.[47,52] This important safeguard ensures prompt recognition and treatment of tachysystole and abnormal FHR patterns.

Regardless of the contraction pattern, any sign of fetal compromise requires immediate discontinuation of the oxytocin infusion. Additional interventions include lateral repositioning of the woman, a 500-mL intravenous fluid bolus of lactated Ringer's solution, and administration of oxygen. A single dose of terbutaline 0.25 mg can be administered subcutaneously if these initial interventions fail to ameliorate the uterine contraction pattern. The midwife should notify the consulting physician and remain at the bedside with the woman until fetal well-being is ensured, in which case the oxytocin infusion can be resumed after 15 to 30 minutes or when indicated. The reader is referred to the *Fetal Assessment During Labor* chapter for suggested tachysystole management guidelines.

In some cases, induction with oxytocin takes longer than anticipated, especially if cervical ripening was clinically contraindicated or was ineffective in improving the Bishop's score. Desensitization ("downregulation") of the oxytocin receptor sites on the uterus from continuous exposure to oxytocin over a prolonged period of time may occur.[49] When this happens, oxytocin becomes less effective and further increases in the dose merely add to the risk of tachysystole and inefficient uterine contraction activity without necessarily dilating the cervix.

Prolonged use of oxytocin can also increase the risk of postpartum hemorrhage from uterine atony for the same reasons. Thus, it is important to be alert for this possibility and consider active management of third-stage labor to minimize the risk for postpartum hemorrhage in women who have been exposed to exogenous oxytocin for several hours (see the *Third Stage of Labor* chapter).

In addition to postpartum hemorrhage, the use of oxytocin is associated with an increased risk of uterine rupture. Uterine rupture in a woman who does not have a scar in the uterus is a rare event in the United States (< 1 incident per 10,000 pregnant women).[54] By comparison, in low-resource areas with limited access to cesarean birth, the incidence of uterine rupture is more common, especially among women with higher parity experiencing an obstructed labor. In developed countries, uterine rupture is almost exclusively associated with women attempting a trial of labor after cesarean (TOLAC). Although oxytocin for induction or labor augmentation is not contraindicated for women who are attempting TOLAC, higher doses significantly increase the risks of uterine rupture and should be avoided.

If the woman's condition is stable and she is not yet in active labor, it is reasonable to discontinue the oxytocin infusion after 10 to 12 hours. This conservative approach will correct any receptor downregulation and enable the woman to rest. It will also reduce the risk of postpartum uterine atony from a prolonged infusion. Moreover, this approach allows time for additional cervical ripening overnight if needed. The oxytocin can then be restarted the next day and the induction plan will proceed accordingly. For some women, achieving a vaginal birth from a labor induction requires considerable patience on the part of the caregivers. The criteria for a diagnosis of "failed induction" are not clearly defined in the literature, and this possibility should be considered only after the woman reaches the active phase of labor.[29]

One last issue with oxytocin is the conflicting goals and miscommunication that sometimes occur between the nurses at the bedside managing the infusion and the ordering providers.[46] Often this conflict revolves around the dosing intervals of the oxytocin infusion. One possible solution is to implement mutually agreed-upon checklist-based protocols for oxytocin administration.[46,47,52] These checklists focus on the fetal and uterine response to oxytocin instead of specifying a specific dosing regimen, allowing time for normal labor progress rather than more oxytocin. Also included are other safety measures such as appropriate staffing ratios and standard order sets for treating tachysystole. Prompt initiation of interventions without additional orders from the provider is an essential component of best practice recommendations for oxytocin use.[52]

Other Methods of Induction

The use of more natural techniques to stimulate labor or facilitate cervical ripening is of interest for many women. In many cases, these methods have been endorsed in an attempt to help women avoid an induction of labor with oxytocin.

Nipple Stimulation

Researchers have evaluated the safety and effectiveness of nipple or breast stimulation as a

method to stimulate or induce labor.[55] Stimulation of the nipples is known to induce the release of endogenous oxytocin from the pituitary gland, which in turn causes uterine contractions similarly to administration of synthetic oxytocin. In fact, nipple stimulation protocols have been used as an alternative to oxytocin administration for performing a contraction stress test. Various techniques have been employed, such as rolling one or both nipples between the fingers or using a manual or electric breast pump.

A systematic review of the available studies on nipple stimulation reported that low-risk women with a favorable cervix who used this technique were likely to be in labor within 72 hours.[55] Other significant findings were a decreased incidence of postpartum hemorrhage and no episodes of uterine tachysystole or abnormal FHR changes. One remaining concern is the effect of nipple stimulation and endogenous oxytocin on placental perfusion. Because the existing evidence has not specifically examined nipple stimulation for women who are at risk for fetal acidemia, its use is discouraged with this population.[55]

Herbal Preparations

Several herbal preparations, such as castor oil, evening primrose oil, raspberry leaf, and blue or black cohosh, have been used for the purposes of stimulating labor. Midwives who recommend herbal preparations believe these methods are safe, are inexpensive, and help women avoid medical induction and prolonged pregnancy.[56] They can also be self-administered by the woman at home or used in a birth center where oxytocin and prostaglandin use is contraindicated. Information regarding herbal methods of labor induction is often shared informally among colleagues and likely based on anecdotal experiences, folklore, and traditional practices. There is wide variation among midwives in how and when these preparations are prescribed.

A review of the literature regarding herbal methods of labor induction reported an overall lack of scientific evidence regarding these treatments' efficacy or clinical benefit to women.[57] In case reports, blue cohosh has been associated with perinatal stroke and acute myocardial infarction; it should not be used.[58] Currently, there is no scientific literature that documents the safety or efficacy of black cohosh. Until scientific studies can be conducted to refute these concerns, blue and black cohosh, either together or in combination with other substances, should not be used in clinical practice. Evening primrose oil and raspberry leaf, in contrast, have demonstrated no evidence of harm over many years of use. Whether they actually cause contractions or promote cervical ripening is not conclusively seen in the evidence, but their use during pregnancy is considered to be safe.[58]

The use of castor oil can be traced back to Egyptian times, and this product is still commonly used today to induce or stimulate labor. Although the exact mechanism of action is not completely understood, ingestion of castor oil produces a powerful cathartic effect that in turn induces uterine contractions. Some women have reported rapid tumultuous labors after ingesting castor oil, and use of this preparation may be associated with an increased risk of meconium-stained amniotic fluid. The evidence from several studies remains inconclusive regarding the effectiveness of castor oil. Although castor oil ingestion is safe for women during pregnancy, midwives who elect to use it for labor induction should be aware of the

inconsistent evidence as well as the lack of standard dosing protocols.

In summary, caution should be exercised when prescribing or recommending alternative methods of cervical ripening or induction of labor not supported in the scientific literature. The midwife should also inform the woman of the known risks, benefits, and safety concerns prior to prescribing or endorsing the use of any herbal preparations.

Labor Abnormalities

The classic abnormalities of labor progress are prolonged latent phase, slow-slope active phase, active-phase arrest, arrest of descent, prolonged second stage, and arrest of descent in the second stage. Second-stage abnormalities are presented in detail in the *Second Stage of Labor and Birth* chapter. Evaluation of labor progress is an ongoing intrapartum assessment, although the relationship between labor duration and maternal and neonatal outcomes is not well understood.[59] Obstructed labor resulting from true cephalopelvic disproportion is a real phenomenon, and neglected obstructed labor is a significant contributor to maternal and neonatal morbidity and mortality in low-resource settings.[60] Primary contributors to this problem are undernourishment in childhood resulting in a small pelvis and lack of access to needed medical care during abnormal labors.

The situation in developed countries is quite different. It is not clear that commonly used frameworks for diagnosing and treating prolonged labor in the United States improve outcomes.[59] Nonprogressive labor is the most common reason for primary cesarean births and is indirectly responsible for many repeat cesareans, and most agree that this condition is overdiagnosed.[61,62]

Many terms are used to denote abnormally slow labor—for example, labor dystocia, dysfunction labor, and failure to progress. There is no consensus on the diagnostic criteria for these terms.[62] New research and expert opinions on the parameters of normal labor progress are reviewed in the *First Stage of Labor* chapter, and questions about the appropriate overall framework for care related to labor progress make this an evolving and complex topic.[63-71]

For many years, assessment of labor progress was based on the work of Friedman, who published original labor curve data in the 1950s.[63] In the Friedman framework, parameters for abnormal labor progress are as follows:[64]

- Prolonged latent phase:
  - Nulliparas: greater than 20 hours
  - Multiparas: greater than 14 hours
- Protracted active phase:
  - Nulliparas: less than 1.2 cm/hr dilation
  - Multiparas: less than 1.5 cm/hr dilation
- Active-phase arrest: no progress in 2 hours

More recent research based on two large data sets, the Collaborative Perinatal Project (CPP) from 1959–1966[65] and the Consortium on Safe Labor (CSL) from 2002–2008,[66] have challenged Friedman's criteria, suggesting that labor progress for contemporary women is actually much slower for both nulliparous and multiparous women. Another key finding is that many women are not in the active phase of labor until their cervices are 6 cm dilated. Currently proposed evidence-based definitions for abnormal labor progress based on the CSL database are as follows:[61,66]

- Nulliparas: less than 0.5 to 0.7 cm/hr dilation; multiparas: 0.5–1.3 cm/hr dilation, with faster dilation as labor progresses
- No application of active labor diagnosis until 6 cm dilation

The differences between the Friedman curve and newer analyses by Zhang et al.[65,66] can be attributed to several factors. Some have proposed that women today are older, heavier, and subject to different intrapartum interventions compared to the women included in Friedman's population studies. Furthermore, Friedman's work was based on direct observation of women in labor, whereas Zhang et al. applied a different statistical analysis to previously collected data. Also debated is optimal timing and type of interventions, including cesarean birth. In the past, recommendations were based on Friedman criterion for protracted and arrested labor. Oxytocin augmentation and amniotomy were often used at this point, with the consensus being that a cesarean was indicated if no additional progress occurred in 2 hours with adequate labor.[67]

There are no currently agreed-upon protocols indicating when interventions should begin. The authors of the consensus document published by ACOG and the Society for Maternal-Fetal Medicine state, "When the first stage of labor is protracted or arrested, oxytocin is commonly recommended."[61] This document also asserts that slow but progressive labor is not an indication for a cesarean section.[61] In addition, it recommends that before a cesarean section for nonprogressive labor is undertaken, the woman should be at 6 cm of cervical dilatation or more, have ruptured membranes, and have no cervical change over 4 hours with adequate uterine activity *or* no cervical change with at least 6 hours of oxytocin with inadequate uterine activity.[61] Neal et al. offer more specific guidance, suggesting that "at more than 5 cm dilatation, oxytocin augmentation may be considered any time there is a more than a 4 h delay in cervical change."[59]

Midwifery Management of Abnormally Slow Labor

Prolonged Latent Phase

However, accurate measurement of the latent phase of labor is problematic, and the relationship between duration of the latent phase and outcomes is not clear.[68]

Management of prolonged latent labor can be particularly challenging. Delaying admission to the birth setting until the active phase of labor is optimal, because earlier admission is associated with an increased risk of a variety of interventions, such as oxytocin augmentation, epidural analgesia, and cesarean birth.[69]

The use of coping techniques at home will be sufficient for some women with long latent phases.[68,69] Among these strategies are the presence of a supportive companion, a warm bath or shower, fluid and food, comfort measures (e.g., massage), ambulation and rhythmic movement, music, and aromatherapy.[70] The woman should be encouraged to stay hydrated, nourished, and rested.

Medications that have a sedative effect are sometimes used to help women sleep.[70] There is a paucity of research on the effectiveness or safety of these agents for treating women during

labor. Some such as diphenhydramine (Benadryl) have a long history of use during pregnancy and appear to be quite safe. Others such as secobarbital (Seconal) have very long half-lives that could adversely affect the newborn so they are no longer in common use. Short-acting non-benzodiazepine sedatives such as zolpidem (Ambien) may be used for this purpose in some locales but no published studies that have assessed either safety or effectiveness have been published.

Qualitative evidence suggests that many women find coping with latent labor at home difficult and stressful, and desire admission earlier than recommended.[68] This is a quandary for midwives, especially when the latent phase is lengthy. Regular phone contact with the midwife, outpatient check-ins, reassurance of normalcy, realistic anticipatory guidance, and emotional support may help many women manage this part of labor at home.

If the woman becomes dehydrated or too sleep deprived secondary to a prolonged latent phase, she may need admission to the hospital. The two treatment options in such a case are (1) therapeutic rest to stop contractions and allow a period of rest or (2) uterotonic drugs to encourage organized effective contractions. It is best to base management decisions on maternal and/or fetal status and maternal preferences, rather than duration of the latent phase.

Therapeutic rest typically involves a single dose of morphine sulfate administered intramuscularly (or intravenously), which is sometimes combined with promethazine (Phenergan) or hydroxyzine (Vistaril).[70] A variety of dosing strategies are used, all of which have a primary goal of inducing heavy sedation or sleep. Commonly encountered maternal side effects include respiratory depression, euphoria, sedation, dizziness, and nausea and vomiting. Neonatal respiratory depression is also a potential concern, especially if labor progresses rapidly if morphine is administered close to the time of birth. In many cases, women managed with therapeutic rest will sleep for several hours and awaken in active labor.

Slow Labor in the Active Phase

A delay in cervical dilation may be a normal variation of a particular woman's labor. Analysis of the CSL database found significant individual variability in the time interval in dilating from one centimeter to the next during the active phase of labor.[66] In addition, no progress for 2 hours, especially before 7 cm dilation, is a common occurrence.[71] Management of slow labor should begin with thorough data collection. Maternal and fetal well-being must be confirmed first, then all factors that might contribute to slow labor progress must be assessed, including physical, psychological, and environmental factors (**Table 29-8**).

Table 29-8	Assessment for Slow Labor Progress

1. Observe the woman for signs of exhaustion, decreased coping, or dehydration.
2. Explore the possibility of an underlying maternal fear or anxiety related to labor or the pending birth to determine ways to improve the woman's coping ability.
3. Assess adequacy of labor support and the woman's environment for factors that may impede labor progress.
4. Check maternal vital signs for fever or tachycardia.
5. Palpate the contractions for frequency and intensity, and note any trends or changes.

6. Reassess estimated fetal weight and fetal lie, presentation, position and attitude with Leopold's maneuvers.
7. Assess fetal well-being with intermittent auscultation or continuous electronic fetal monitoring.
8. Review the labor progress up until this point.
9. If the membranes are not ruptured, perform a cervical examination and carefully assess dilation, effacement, station, and position of the fetal head. Note any asynclitism, molding, or caput.
10. During the cervical examination, perform clinical pelvimetry; note any obvious narrowing of the pelvic diameters.
11. If the membranes are ruptured, perform this examination only if clinically indicated.

Abbreviations: TOLAC, trial of labor after cesarean; VBAC, vaginal birth after cesarean.

Continued expectant management is reasonable if there are no clinical indications to expedite birth. Strategies to stimulate or augment labor should be presented to the woman, and the risks and benefits of each option reviewed. Depending on the woman's preferences, the least invasive strategies should be attempted first. For example, if the woman is rested and coping well, ambulation or position changes should be encouraged.

Theoretically labor progress may slow or stall secondary to acute stress, and some authors have postulated that fear or anxiety can interfere with labor progress. The catecholamines that are released during the stress response—that is, norepinephrine and epinephrine—normally have an inhibitory or tocolytic effect on uterine contractility. If labor, fatigue, and pain cause an acute stress response, a diminution of uterine contractility may occur. A few small studies have correlated plasma epinephrine levels and uterine contractility, with the results supporting this hypothesis.[72] Nevertheless, it is not known if beta-adrenergic receptors for endogenous catecholamines are significantly upregulated in the uterus during term labor, and the research that supports this theory is not robust. Thus, the relationship between significant fear or anxiety and slow labor progress remains somewhat theoretical. Strategies that promote a sense of emotional well-being and safety are certainly good options if labor progress is slow. Continuous labor support—especially the therapeutic presence of the midwife, decreasing unnecessary stimulation from caregivers, low lighting, and privacy—may help decrease the physiologic stress response.

Relief of pain is another important component of managing slow labor. Unrelieved pain is also associated with increased levels of circulating catecholamines. Hydrotherapy can be very effective in decreasing pain and increasing comfort. Inability to cope may indicate the need for medication and, for some women, epidural anesthesia. While this strategy may increase the likelihood of other interventions being used to stimulate labor, ensuring adequate relief of pain is always a priority.

Malpositions such as occiput posterior position, and other normal variations in fetopelvic relationships such as asynclitism are common causes of slow labor. Watchful waiting and position changes that increase pelvic diameters are suggested approaches. Most fetuses in an occiput transverse or occiput posterior position will rotate to occiput anterior prior to birth. Persistent fetal malpositions are addressed in the *Second Stage of Labor and Birth* chapter.

Amniotomy can also stimulate or augment labor when slowed progress is encountered. This procedure is not associated with a shortening of the duration of labor in women who start labor spontaneously and progress normally.[73] In contrast, in women whose labor is induced and

those who are experiencing slow progress, amniotomy with oxytocin augmentation is associated with a shorter duration of labor.[74]

A final strategy for managing slow labor is oxytocin augmentation. The same cautions and clinical considerations exist regardless of whether oxytocin is used for augmentation or induction of labor. Insertion of an intrauterine pressure catheter is not mandatory unless external monitoring is unable to detect contraction frequency. The consulting physician should be informed of the ongoing plan of care during labor augmentation with oxytocin and the woman's labor progress and fetal response monitored closely.

Often there are many possible appropriate strategies for slow labor. Shared decision making should be used, as the woman's preferences are a key aspect of clinical decision making in this situation.

Active-Phase Arrest

Active-phase arrest is diagnosed when a woman is at a cervical dilation of 6 cm or more with ruptured membranes and no cervical change for 4 hours or more in the presence of adequate uterine contractions (> 200 Montevideo units) or no cervical change in 6 hours or more in the presence of inadequate contractions.[61] When active-phase arrest is diagnosed, physician referral is required, as the treatment is cesarean birth. Possible etiologies of active phase arrest are cephalopelvic disproportion or deep transverse arrest wherein the fetus in a vertex presentation cannot rotate from transverse to occiput anterior or occiput posterior. Cephalopelvic disproportion can be secondary to maternal pelvic architecture or fetal size or malposition.

Trial of Labor After Cesarean

For the past several decades, women presenting with a history of one or more previous cesareans have faced a series of changing opinions regarding the best mode of birth during subsequent pregnancies. Prior to the early 1980s, the predominant philosophy was "once a cesarean, always a cesarean." Early reports of successful vaginal birth after cesarean (VBAC), however, began to challenge this long-standing practice. In 1980, the National Institutes of Health (NIH) published a landmark statement endorsing a trial of labor for women who had one previous lower transverse cesarean birth.[75] Over the next 10 years, VBAC continued to grow in popularity, with several large studies reporting a 60% to 80% success rate for women who underwent a trial of labor after cesarean (TOLAC).[76] These studies also demonstrated that planned repeat cesarean delivery (PRCD) was associated with more maternal morbidity than a TOLAC and subsequent VBAC.

The NIH had hoped promoting a trial of labor would reduce rising cesarean birth rates, along with their associated costs in terms of morbidity and economic expense. This strategy appeared to be successful, and by 1996, the rate of cesarean births in the United States reached an all-time contemporary low of 20.7%.[76] As more women underwent TOLAC, reports of uterine rupture during a trial of labor emerged, leading to increased safety concerns. In 1996, a large clinical trial was published that examined a composite measure of serious maternal morbidity including uterine rupture, hysterectomy, and operative injury. The absolute risk of this measure was found to be 1.6% in women who underwent TOLAC and 0.8% in women who had a PRCD.[77] The risk of these complications was found to be much higher in the 40% of women in the TOLAC group who had an unplanned repeat cesarean birth.

This study, which was widely publicized, reported the relative risk of a doubling of serious maternal complications with TOLAC versus PRCD. Almost immediately, enthusiasm for TOLAC began to wane and VBAC rates steadily fell. Concern about the risk of uterine rupture and its associated liability resulted in ACOG guidelines that recommended the immediate in-house availability of an obstetrician and an anesthesiologist to perform an emergent cesarean birth if needed.[78] Many hospitals and providers subsequently stopped offering TOLAC services, radically altering women's childbirth choices. By 2007, cesarean birth rates had risen to 32.8%; in turn, VBAC rates plummeted to 8.9%.[79] While many factors have been cited for the cesarean epidemic, decreased access to available TOLAC services, particularly in rural areas that do not have immediate in-house anesthesia availability, is a frequently cited cause of this unfortunate trend.

Concerns about the rising primary cesarean birth rates and the associated morbidities, particularly the increase in the incidence of placenta previa and placenta accreta in subsequent pregnancies led the NIH to revisit the comparative safety of having a VBAC versus PRCD. In 2010, the NIH Consensus Development Conference Statement on this topic was published; it concluded that women with a previous low transverse cesarean birth can be safely offered a trial of labor when no other contraindications to vaginal birth exist.[79] The NIH statement also encouraged obstetric providers to improve access to TOLAC services and support women's

preferences when possible. ACNM published a position statement and an updated clinical practice bulletin that supports the NIH's consensus report.[80] In 2017, ACOG published revised guidelines that recommend women who are candidates for TOLAC can be safely offered TOLAC in Level 1 hospital settings.[81] These settings do not require immediate in-house anesthesia but do have the ability to initiate an emergency cesarean in life-threatening situations.[81]

Risks of TOLAC and PRCD

The comparative risks of TOLAC versus PRCD are presented in the *Pregnancy-Related Conditions* chapter, reflecting the reality that discussion of these issues begins during prenatal care. The most serious and catastrophic risk for a woman who elects TOLAC is uterine rupture. Generally speaking, the term *uterine rupture* describes an anatomic separation of the uterine muscle.[76,79,81] This outcome can be further differentiated between uterine scar dehiscence and full separation of all uterine layers. Occult scar dehiscence does not include the serosa layer and is an incidental, asymptomatic finding with no adverse maternal or fetal consequences. A complete uterine rupture, in contrast, is a symptomatic, life-threatening emergency. Currently, the risk of uterine rupture is cited as 0.4% to 0.7% for women attempting TOLAC, compared to 0.03% in women who opt for PRCD.[79] Uterine rupture is associated with a 14% to 33% rate of hysterectomy and a 6% intrapartum fetal death rate (or 2.9 fetal deaths per 10,000 women who have a TOLAC).[79]

PRCD has risks for both the women during the current pregnancy and any subsequent pregnancy. There is an increased risk of abnormal placentation (placenta previa, accreta, and abruption) with a history of cesarean birth, and this risk increases with each cesarean birth. For example, after one cesarean birth, the risk of placenta previa is 9 per 1000, but this risk increases to 17 per 1000 after two cesareans.[82]

A history of previous classical or "T" uterine incision, previous uterine rupture, or any type of fundal uterine surgery (i.e., myomectomy), significantly increases the risk for uterine rupture.[81] Women presenting for prenatal care with any of these risk factors are not candidates for TOLAC; instead, it is recommended that they undergo a PRCD. The optimal gestation age for PRCD is 39 weeks.[82] In addition, these women require prompt evaluation in the hospital with continuous fetal monitoring and physician consultation should regular contractions occur before the scheduled date of surgery.

Factors such as a history of two or more previous (low transverse) cesarean births, or previous preterm cesarean birth, increase the risks of uterine rupture to varying degrees. A review of the existing evidence found weak associations for these factors and concluded that evidence for most of the factors is limited.[81] Consequently, women with these obstetric histories can now safely be offered a TOLAC if desired and after a discussion about her individualized risks. These women should receive prenatal counseling from a physician given they have conditions that may increase the risk of uterine rupture to some extent.

Induction or Augmentation of Labor During TOLAC

Abnormal labor progress is associated with a small increased risk of uterine rupture.[75,81] Similarly some studies have shown a slightly increased risk of uterine rupture when oxytocin is used for augmentation of labor in women who have a TOLAC.[75] The increased risk of uterine rupture associated with oxytocin augmentation is minimal, however, and does not rule out its use when medically indicated.[75,81] Because the upper limits for oxytocin dosing with TOLAC have not been established, a conservative approach is preferred, accompanied by close monitoring of fetal well-being, uterine activity, and labor progress.

Similarly, the risk of uterine rupture is higher in women whose labor is induced with oxytocin, but the absolute risks are still low.[81] Notably, induced labor is less likely to result in a successful VBAC, especially if the woman has an unfavorable cervix.[75] Therefore induction of labor should be considered only when medically indicated and only in hospital settings where physician consultation for a cesarean birth is available.

The use of cervical ripening agents for women who desire TOLAC is more controversial. Prostaglandins E_1 (misoprostol/Cytotec) and E_2 (Cervidil and Prepidil) are commonly used to facilitate cervical remodeling and have been shown to improve labor induction success rates. Interpretation of the evidence is made difficult by inconsistent study results and design limitations such as grouping of different types of prostaglandins together, use of birth certificate data (which are known to have poor accuracy), and underpowered for detection of relevant outcomes.[81] Even so, based on several small studies showing an increased rate of uterine rupture following use of misoprostol for cervical ripening in women who had a prior cesarean, this medication is now considered contraindicated.[81] Due to limited evidence regarding the effects of prostaglandin E_2 in women who have a uterine scar, use of this medication is discouraged.[81] Mechanical methods (i.e., cervical Foley balloon) have not been associated with increased risks of uterine rupture and can be used for cervical ripening.[81]

Intrapartum Management for Women During TOLAC

Table 29-9 outlines intrapartum management guidelines for women attempting TOLAC. When a woman with a history of previous cesarean birth presents for a labor evaluation, the prenatal record should be reviewed, along with any previously discussed labor management options. The woman's continued desire for TOLAC should be reaffirmed and the informed consent documentation reviewed. The intrapartum database should also include a thorough review of her obstetric history, paying particular attention to the indications for and circumstances surrounding the previous cesarean birth. Equally important is confirming the type of uterine incision (if known) and ascertaining whether the woman has undergone any other uterine surgeries since her last birth. Lastly, a consulting physician should be notified if there is any contraindication to VBAC or if the woman is opting for PRCD.

Table 29-9 Intrapartum Management Guidelines for Women Attempting Trial of Labor After Cesarean

1. A consulting physician should be notified when a woman desiring TOLAC is admitted in labor.
2. Intravenous access (i.e., heparin or saline lock) may be required according to institutional policies.

3. Clear liquid intake is not contraindicated; however, some institutional policies may restrict this intake to ice chips or sips of water.
4. More frequent fetal heart rate monitoring is required—either continuous electronic monitoring or intermittent monitoring per high-risk guidelines (i.e., every 15 minutes in active labor and every 5 minutes in second-stage labor). A telemetry monitor can be used to encourage freedom of movement.
5. The woman should be monitored closely for indications of uterine rupture. The most common initial sign is either recurrent fetal heart rate decelerations that become progressively deeper or an abrupt fetal heart rate bradycardia. Other signs include changes or cessation of uterine contractions, vaginal bleeding, or a sudden loss of fetal station.
6. Epidural anesthesia is not contraindicated and will not mask the most common signs and symptoms of uterine rupture.
7. Labor progress should be closely monitored for signs of abnormally slow progress. Oxytocin should be used with caution, and only after other nonpharmacologic methods to promote labor progress have been attempted. Physician consultation should be obtained prior to initiating labor augmentation with oxytocin.
8. High-dose oxytocin protocols are contraindicated.
9. Intrauterine pressure catheters have not been shown to accurately depict an impending uterine rupture and should not be used solely for that purpose.
10. Hydrotherapy (i.e., tub or shower) is not contraindicated as long as waterproof fetal monitoring is available, although it is frequently restricted according to individual policies.
11. There are no contraindications to alternative positions for birth as long as fetal assessment guidelines are followed.
12. Management of third-stage labor is the same following VBAC as it is following a normal vaginal birth. The midwife and woman can opt for either expectant or active management of the third stage. There is no need to explore the uterine scar for signs of asymptomatic dehiscence after the delivery of the placenta.
13. Women with a previous uterine scar have an increased risk of abnormal placentation (e.g., placenta accreta). A physician should be consulted for a retained placenta prior to any attempts for manual removal.

Midwifery management for women in labor who desire TOLAC is similar to the care of any laboring woman with a few exceptions, including the recommendation for continuous FHR and uterine contraction monitoring and possibly a requirement for intravenous access. In addition, women who have experienced a previous unplanned cesarean birth often present with intense feelings regarding their past birth. They may have psychological milestones to overcome at the point in labor in which the events leading to the cesarean birth occurred. The midwifery model of care supports practices that promote normal labor and birth and are beneficial for women who desire TOLAC. All interventions, therefore, should be evaluated for safety and interference with normal labor progress and mechanisms.

Intrapartum Management for Women with Coexisting Medical Conditions

Two common medical conditions that can have adverse effects for a pregnant woman and her fetus are diabetes and hypertension. When caring for a woman with diabetes or hypertension, a collaborative plan of care between the midwife and a consulting obstetrician should be in place. As these women enter labor, the balance of management authority will greatly depend on individual policies, the evolving clinical situation, and the experience of the midwife. It is important for midwives to have knowledge of what to expect for these women and to recognize that the intrapartum clinical course could change suddenly, necessitating immediate referral of care to the obstetrician. Ongoing and clear communication between the physician and the midwife is paramount throughout labor to ensure the best outcome for the mother and her infant. When midwives collaborate in the care of women with coexisting medical complications, the midwife often monitors and manages labor progress, while the physician monitors and manages interventions required to minimize adverse effects of the medical condition. For example, if the woman has diabetes, the midwife may care for her during labor and birth, while the physician oversees administration of insulin and other tests to monitor diabetes.

Many other medical conditions can adversely affect pregnancy, including epilepsy, autoimmune disorders, and heart conditions. Every possible condition cannot be addressed here, but management is always contingent on knowledge of the physiology of the disorder, diagnosis, and the effects on pregnancy. The midwife also needs to know when to obtain a consultation and/or transfer care of the woman. In this section, diabetes and hypertension are used as examples of the midwifery management process when caring for a woman who has a coexisting medical condition.

Women with Diabetes

Approximately 6% to 7% of pregnancies in the United States occur in women with diabetes, with 90% of the affected women having gestational diabetes.[83] For women with well-controlled, pregestational diabetes, induction of labor is recommended between 39 and 40 weeks' gestation.[83] The optimal timing for birth for women with well-controlled gestational diabetes is not clear.[83] A plan for fetal surveillance and timing of birth should be developed in collaboration with the woman and consulting obstetrician.

Women with either pregestational or gestational diabetes have an increased risk of shoulder dystocia during delivery. This trend reflects the increased risk of macrosomia and a tendency for the infants of diabetic mothers to have larger shoulder diameters at a given weight.[84] Prediction of macrosomia via ultrasound or clinical palpation is quite inexact. Induction of labor is not recommended for suspected macrosomia. Nevertheless, the option of cesarean birth is offered to women with diabetes who have a fetus with an estimated fetal weight of 4500 grams or more.[84] This practice is based on evidence showing a higher risk of brachial plexus injury in the infants born to women in this cohort. **Appendix 29A** reviews the management of shoulder dystocia. Fetal lung maturity may be delayed in the infants of women

with diabetes, and these seemingly full-term infants can exhibit respiratory distress and other related complications immediately following birth.

During labor, monitoring the woman's blood glucose and maintaining glycemic control have been shown to reduce the incidence of neonatal hypoglycemia.[83] For women who are euglycemic with dietary changes only, it may not be necessary to monitor glucose levels during labor. Women who are using insulin or oral glycemic agents, however, will require finger-stick glucometer testing of their blood glucose approximately every 2 hours. Any evidence of intrapartum hyperglycemia should be treated promptly with intravenous insulin, balanced with dextrose 5% in lactated Ringer's solution. The goal is to maintain the woman's blood glucose between 80 and 110 mg/dL.[83] Institutional variations on these guidelines may exist, and the midwife should develop the most appropriate plan of care with a consulting physician. When a woman in labor has an insulin infusion, she is best cared for collaboratively by a physician who manages the diabetes and a midwife who manages her labor progress.

Careful assessment of fetal size by Leopold's maneuvers is performed when the woman is admitted, and labor progress is monitored closely. Continuous fetal monitoring is required if an insulin infusion is administered. The midwife should be prepared for the possibility of shoulder dystocia at the time of birth and have a low threshold for requesting the presence of the consulting obstetrician during the second stage of labor. The pediatric team should also be notified, especially if the woman has poor glycemic control or fetal lung immaturity is a possibility.

Women with a Hypertensive Disorder

The diagnostic criteria for hypertensive disorders in pregnancy are described in the *Medical Complications in Pregnancy* chapter. In all cases, these diagnoses may become medical indications for delivery, but the timing will vary according to the severity of the woman's condition and the gestational age of her fetus. Although some fetal risks are associated with these disorders, maternal mortality and morbidity are the primary concern; treatment focuses on preventing end-organ damage in the woman. It is most important for clinicians to recognize that hypertension and preeclampsia exist on a continuum that is often unpredictable. For this reason, women admitted with either of these diagnoses require vigilant monitoring during labor for subtle changes or a sudden acceleration of worsening symptoms. The midwife works closely with the collaborating physician to develop the most appropriate plan of care, especially if the woman is diagnosed with preeclampsia.

Intrapartum considerations include an ongoing assessment of the woman for the presence of headache, visual changes, or epigastric pain. Any headache should be taken seriously and reported to the consulting physician, especially if unrelieved with oral acetaminophen. Visual changes such as scotomata (loss of visual field) or scintillating spots and epigastric or right upper quadrant pain are also worrisome symptoms that require prompt evaluation and consultation with the physician. Careful monitoring of fluid balance is essential as well. Although women with preeclampsia may have intravascular volume depletion, they are at risk for pulmonary edema secondary to the need for intravenous fluids in the presence of impaired kidney function. **Table 29-10** outlines specific assessments that should be included in the plan

of care during labor, and **Table 29-11** describes how to determine the presence or absence of clonus.

Table 29-10 Labor Assessment for Women with Preeclampsia

1. Hourly blood pressure monitoring[a]:
   a. Any result higher than or equal to 160 mm Hg systolic or 110 mm Hg diastolic requires immediate physician consultation and administration of an intravenous antihypertensive medication.[85]
2. Lung auscultation and/or pulse oximetry:
   a. Any shortness of breath, abnormal breath sounds (crackles, wheezes), or other signs of pulmonary edema require the immediate presence of a physician.
   b. Obtain pulse oximetry if the woman has any shortness of breath.
3. Deep tendon reflexes:
   a. Hyperreflexia or the presence of clonus requires physician consultation. (See **Table 29-11** for information on assessment of clonus.)
4. Serum creatinine, AST, complete blood count (hemoglobin, hematocrit, and platelets):
   a. Obtain on admission and every 8 hours per practice/institutional guidelines. Report abnormalities to a consulting physician.
5. Strict intake/output:
   a. Measure urine output at least every 2 to 4 hours. If the urine output is averaging 30 mL/hour or less, notify the physician.
   b. Carefully monitor intravenous and oral fluids.
6. If magnesium sulfate is infusing:
   a. Perform hourly assessments of respiratory rate, deep tendon reflexes, and urine output. The infusion should be discontinued and a physician notified immediately for any signs of magnesium toxicity (respiratory rate less than 12 breaths/minute, absent or diminished deep tendon reflexes, or urine output less than 30 mL/hour).
   b. The antidote for magnesium toxicity is calcium gluconate 10 mL of a 10% solution administered intravenously over 3 minutes.

Abbreviation: AST, aspartate aminotransferase.

[a] Manual blood pressure measurements are preferred, as they are the most accurate.

Table 29-11 Assessing for Clonus

What Is Clonus?
Clonus is involuntary, rapid, repetitive, rhythmical contractions and relaxations of a muscle when it is sharply stretched and the stretch is maintained in either flexion or extension. Clonus can be elicited at a number of sites; in obstetrics, most commonly the ankle is used.
What Causes Clonus?
The presence of clonus is associated with a hyperreflexive state and could indicate abnormal central nervous system (CNS) excitability. It is always associated with abnormal (+4) deep tendon reflexes and may be a precursor to an eclamptic seizure.
Assessment for Clonus

1. Position the woman so her knee is partially flexed. Support this position with one hand underneath the bend in her knee.
2. With the other hand grasping her foot, sharply dorsiflex the foot and maintain pressure to keep it in dorsiflexion.
3. Beats of clonus will be seen and felt as the muscle contractions and relaxations cause rhythmical alternation between dorsiflexion and plantar flexion. The muscles being stretched are the same as for the ankle jerk reflex —the gastrocnemius and soleus muscles.

Severe hypertension and eclampsia are two of the most serious consequences of preeclampsia. The National Partnership for Maternal Safety has a consensus bundle (set of evidence-based guidelines) of recommendations for recognizing early warning signs (triggers) of these conditions and treating severe hypertension (**Table 29-12**).[85,86] Other evidence-based protocols are listed in the Resources section at the end of this chapter.

Table 29-12 Treatment of Severe Hypertension

Drug: Generic (Brand)	Dose	Contraindications[a]
Hydralazine (Apresoline)	5–10 mg IV every 20 minutes Maximum total dose: 20 mg in first hour	Tachycardia
Labetalol (Normodyne, Trandate)	20 mg IV bolus Followed by 40 mg if not effective in 10 minutes Followed by 80 mg if not effective in 10 minutes Maximum total dose: 300 mg in first hour	Asthma, congestive heart failure
Nifedipine	10–20 mg orally every 30 minutes Maximum total dose 50 mg in first hour	Tachycardia

Abbreviation: IV, intravenous.

Note: If blood pressure is ≥ 160 mm Hg systolic or ≥ 110 mm Hg diastolic, verify within 15 minutes. If confirmed by a second reading, administer a hypertensive within 30–60 minutes.

[a] Contraindications may be relative contraindications depending on the clinical condition.

Based on American College of Obstetricians and Gynecologists. *Hypertension in Pregnancy.* Washington, DC: American College of Obstetricians and Gynecologists; 2013[85]; Bernstein PS, Martin JN Jr, Barton JR, et al. National Partnership for Maternal Safety: consensus bundle on severe hypertension during pregnancy and the postpartum period. *Obstet Gynecol.* 2017;130(2):347-357.[86]

Magnesium sulfate remains the standard of care for the prevention and treatment of eclampsia for women who have preeclampsia with severe features.[85,86] Magnesium sulfate is administered as a bolus of 4–6 gm in 100 mL over 20 minutes, followed by an intravenous infusion of 2 gm per hour throughout labor and for 24 hours post birth. When preeclampsia occurs without severe features, magnesium sulfate therapy is not recommended.[85,86] However, progression of preeclampsia can occur suddenly, and the woman must be monitored very closely for any such changes.

Deep tendon reflexes are part of both the initial evaluation and ongoing assessments. Reflexes are evaluated on a scale of 0 to 4+:

0: absent; no response
1+: decreased; diminished; sluggish
2+: normal; average
3+: brisk
4+: very brisk; hyperactive (usually associated with clonus)

Reflexes designated as 1+ are low-normal reflexes; 3+ reflexes are more brisk than the average reflex response and indicate the possible but not absolute presence of disease; 0 and 4+ reflexes are definitely abnormal and indicate disease requiring physician consultation. Normally, deep tendon reflexes are evaluated as 1+ or 2+. Hyperreflexia (i.e., 3+ or more) is one indication that a seizure is imminent; thus, hyperreflexia is an important piece of information to obtain when a woman presents with hypertension. Conversely, a sign of magnesium toxicity is absent or depressed deep tendon reflexes. Therefore, when magnesium sulfate is infusing, deep tendon reflexes are assessed hourly.

Obstetric Emergencies

Midwives in clinical practice will inevitably encounter an obstetric emergency. Fortunately, most obstetric emergencies are rare occurrences, and in some cases, they can be anticipated. Regardless, midwives are responsible for the care of women during the intrapartum period, which requires a thorough understanding of how to manage emergent events during labor and birth. Prompt recognition and immediate action are imperative until the situation is resolved or the consulting physician can assume management. The following sections review the clinical management for several intrapartum emergencies, including intrapartum hemorrhage, shoulder dystocia, prolapsed umbilical cord, twin gestation, and breech birth.

Recent studies of maternal morbidity and mortality suggest that 40% to 50% of maternal deaths are preventable.[87] Delays in recognition and treatment have prompted the development of early warning signs and rapid response teams to help practitioners more effectively anticipate and respond to obstetric emergencies. Maternal early warning triggers that require immediate attention are listed in **Table 29-13**. All maternity care providers should know these signs and the plans for intervention. Resources for learning more about maternal early warning systems are listed at the end of this chapter.

Table 29-13 Maternal Early Warning Criteria

Sign or Symptom	Definition
Blood pressure	Systolic: < 90 or > 160 mm Hg
	Diastolic: > 100 mm Hg
Heart rate	< 50 or > 120 beats/minute
Respiratory rate	< 10 or > 30 breaths/minute
Maternal symptoms	Agitation, confusion, unresponsiveness
	If preeclampsia: nonremitting headache or shortness of breath
Oxygen saturation at room air at sea level	< 95%
Oliguria	< 35 mL/hr for > 2 hours

Modified with permission from Mhyre JM, D'Oria R, Hameed AB, et al. The maternal early warning criteria: a proposal from the National Partnership for Maternal Safety. *Obstet Gynecol.* 2014;124(4):782-786.[87]

Intrapartum Hemorrhage

The differential diagnoses for vaginal bleeding in the second or third trimester include placenta previa, placental abruption, uterine rupture, and vasa previa. The midwife's role in the care of a woman who is bleeding is to initiate stabilization measures until the collaborating physician can take over the primary management. Anesthesia specialists, the operating room team, and the neonatal/pediatric team should also be mobilized and on standby for an emergent cesarean birth and possible neonatal resuscitation. If the woman is hemodynamically unstable or the fetus is in jeopardy, birth will be expedited, regardless of gestational age.

Initial evaluation of hemodynamic status includes assessment of vital signs, mental status,

and skin color (pallor), as well as a visual evaluation of blood loss. The consulting physician is called for an immediate bedside consultation. If there is evidence of significant blood loss on the woman's clothes or body with any signs of hemodynamic compromise, two large-bore intravenous lines should be started. The woman should be given oxygen and placed on continuous electronic fetal monitoring. Laboratory evaluation includes a complete blood count, coagulation studies, blood type, antibody screen, and cross-match for a minimum of 4 units of blood if the woman is actively bleeding. In addition, a Kleihauer–Betke test should be obtained on all women who are Rh negative to quantify the degree of fetomaternal transfusion to guide the dosing of Rh-immune globulin (RhoGAM).

No digital examinations should be performed when a woman presents with vaginal bleeding. Prenatal ultrasound records should be obtained and reviewed as quickly as possible. If previous ultrasound studies have confirmed a normal placental location, placenta previa can be ruled out, but other possibilities such as placental abruption or vasa previa should be considered.

Placenta Previa

Placenta previa may cause a small amount of vaginal bleeding, or it may result in acute hemorrhage. In the majority of cases, women with placenta previa will present with an initial episode of painless vaginal bleeding. During this first episode, the bleeding usually stops and the woman and fetus are stable. Expectant management in the hospital is initiated in such a case. During this hospitalization, the woman is monitored for signs of labor and, depending on the fetus's gestational age, steroids may be administered to enhance fetal lung maturity and/or magnesium sulfate administered for fetal neuroprotection.

In case of placenta previa, the woman's care is managed by a consulting physician. The midwife may continue in a collaborative role to provide emotional support and anticipatory guidance. Preparation for breastfeeding and parenting as well as family adjustments to hospitalization are an important midwifery component of the woman's plan of care.

Placental Abruption (Abruptio Placentae)

One of the leading causes of obstetric hemorrhage in the second and third trimesters is placental abruption, defined as a premature separation of a normally implanted placenta.[88] Placental abruption occurs in approximately 1% of all pregnancies and is associated with significant perinatal mortality and morbidity.[89,90]

In most cases of abruption, bleeding occurs between the membranes and the decidua, and passes through the cervix into the vagina. Less commonly, the abruption is concealed, such that the blood accumulates behind the placenta with no obvious vaginal bleeding. In such a case, the blood may penetrate through the uterine decidua and escape into the peritoneum. This phenomenon is also termed a Couvelaire uterus.

An abruption can be either total (involving the entire placenta) or partial (involving only a portion of the placenta) (**Figure 29-3**). A total abruption is a catastrophic obstetric event, often leading to fetal death and significant maternal morbidity.

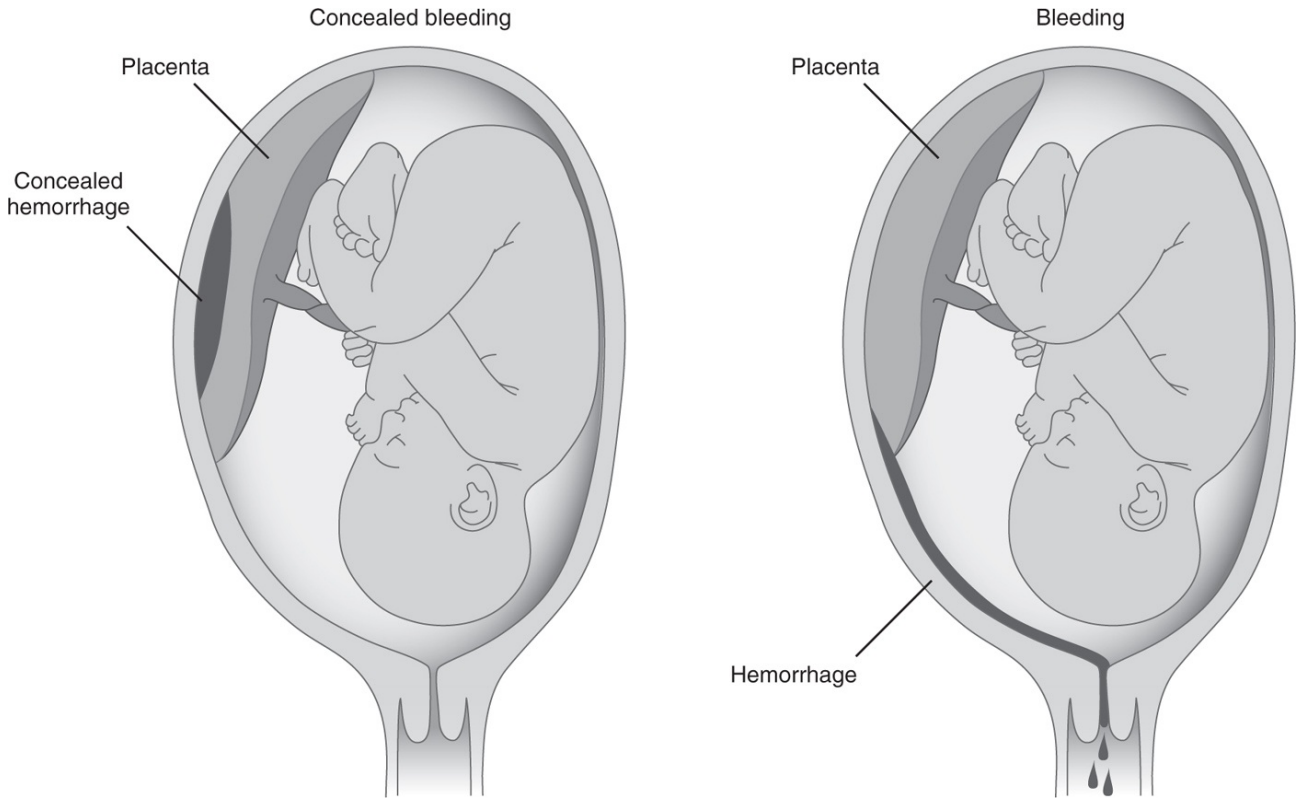

Figure 29-3 Placental abruption.

Although the specific etiology of abruption is unknown, several factors associated with it have been identified (**Table 29-14**). The most common of these risk factors is hypertensive disorders, especially chronic hypertension with superimposed preeclampsia.[89,90] A history of previous abruption, maternal smoking, and cocaine use also significantly increase the risks of placental abruption. In addition, any maternal trauma (e.g., fall, abdominal injury, intimate-partner violence, or motor vehicle accident) warrants an evaluation in the hospital to rule out an abruption. Women who are at more than 24 weeks' gestation should have continuous fetal monitoring for a minimum of 4 hours following trauma to the abdomen. If more than 6 contractions occur in any given hour, the monitoring should be continued for 24 hours.

Table 29-14	Risk Factors for Placental Abruption
Maternal Risks	
Advanced maternal age	
Cocaine use	
Smoking during pregnancy	
Obstetric Risk Factors	
Chorioamnionitis	
Fetal growth restriction	
History of placental abruption	
Hypertensive disorders (chronic, gestational, preeclampsia)	
Multifetal gestation	

Premature rupture of membranes
Polyhydramnios
Thrombophilias
Acute Etiology
Trauma (fall, abdominal injury, motor vehicle accident)
External cephalic version for breech presentation

Based on Oyelese Y, Ananth CV. Placental abruption. *Obstet Gynecol*. 2006:108:1005-1016.[89]; Hladky K, Yankowitz J, Hansen WF. Placental abruption. *Obstet Gynecol Surv*. 2002;57(5):299-305.[90]

The clinical presentation of an abruption depends on the degree of separation and blood loss. Maternal symptoms can vary widely, from mild generalized back discomfort or abdominal cramping to the classic symptoms of vaginal bleeding and severe abdominal pain. Early signs of an abruption can mimic those of labor, and the woman may report periodic mild contractions with what may be perceived as bloody show or bloody amniotic fluid. Low backache may be the only symptom if the placenta is posterior and there is a concealed abruption. The woman may report decreased fetal movement or even a recent surge in fetal activity.

On examination, the woman's demeanor or distress may be out of proportion to the objective clinical signs. The maternal vital signs may be normal with no obvious signs of hemodynamic compromise. The abdomen may be mildly tender with palpable contractions, or it may feel firm, rigid, and diffusely painful. A pelvic examination may reveal minimal to no bleeding, but this will not correlate with the amount of blood loss from a concealed hemorrhage. In most cases, frequent, low-amplitude contractions are seen on the external fetal monitor. Fetal status will also greatly depend on the degree of separation and blood loss. Thus, a variety of FHR patterns have been associated with a placental abruption, including recurrent late or variable decelerations, loss of FHR variability, bradycardia, or sinusoidal pattern.[89] Fetal demise is associated with more than a 50% placental separation; rarely does this degree of abruption occur without other overt symptoms.[89]

Ultrasonography is rarely helpful in confirming the diagnosis of placental abruption or in determining the degree of separation. Research has found that the sonographic appearance of placental separation varies considerably depending on how much time has passed from the acute bleeding event.[89] Ultrasound evaluation of a pregnant woman who presents with vaginal bleeding, however, will identify the placental location and the presence of a placenta previa. Although some degree of separation may be seen with placenta previa, it is considered a distinctly separate diagnosis and would, in effect, rule out placental abruption as the cause of bleeding.

When a woman presents with symptoms of abruption, she should immediately be assessed for signs of hemodynamic compromise and the fetus assessed for signs that suggest an increased risk for fetal acidemia. The continued management will depend in part on the gestational age and in part on the condition of the woman and fetus. The consulting physician should be notified immediately of the midwife's clinical assessment and evaluation and seek to determine the most appropriate plan of care. The midwife should also initiate the maternal/fetal stabilization measures and laboratory assessments discussed in the previous

section.

Although management may vary depending on the degree of maternal/fetal compromise, a diagnosis of placental abruption near term will warrant an expedited birth. In many cases, the placental abruption will stimulate vigorous contractions, with labor then rapidly progressing on its own. The midwife can collaboratively manage this situation with a consulting physician and conduct the birth as planned. During labor, the fetus should be monitored continuously and any signs of fetal compromise promptly reported to the physician. Even with a mild abruption, the situation could deteriorate rapidly, and the woman is at significant risk for coagulopathy and hypovolemic shock. In addition to blood transfusions, the woman may need aggressive replacement of coagulation factors. After the birth, the placenta should be sent to pathology and the woman closely monitored collaboratively with a physician until her condition stabilizes.

Prolapsed Umbilical Cord

There are three types of umbilical cord prolapse: occult, funic, and overt. An *occult* cord prolapse occurs when the umbilical cord is compressed alongside the presenting part in the lower uterine segment or inner cervix. The cord may not be palpable during a cervical examination but will often cause variable decelerations or FHR bradycardia similar to that seen with umbilical cord compression. In a *funic* umbilical cord prolapse, the cord is palpable in front of the presenting part. In an *overt* umbilical cord prolapse, the cord slips completely out of the uterus through the cervix and may be protruding at the vaginal introitus. Variant FHR patterns may be present depending on the degree of cord compression from the presenting part.

When a frank or complete umbilical cord prolapse is encountered, the woman will need an emergent cesarean birth and immediate interventions to improve fetal oxygenation. Risk factors and emergency management of a prolapsed umbilical cord are outlined in **Appendix 29B**.

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE) is a rare obstetrical emergency that may occur from the onset of an apparently uncomplicated labor to within 30 minutes of placental expulsion. The incidence in the United States is 5.1% in 100,000 births.[91] AFE is characterized by sudden cardiorespiratory arrest that might include hypotension, dyspnea, and cyanosis.[92] Blood pressure falls rapidly and peripheral S_PO_2 is less than 90%. New uniform diagnostic criteria specify that there was no fever during labor and that disseminated intravascular coagulation (DIC) signs and symptoms become apparent before coagulopathy could be attributed to acute blood loss or shock-related consumptive coagulopathy.[92]

Clinically, a woman with AFE has sudden respiratory distress with simultaneous cardiovascular system deterioration. The cause of AFE was previously thought to be mechanical obstruction of pulmonary vasculature by fetal cells in amniotic fluid that had sudden inflow to maternal circulation. Pulmonary vasospasm documented during autopsies indicates an anaphylactoid reaction to fetal cells, therefore, AFE is now thought of as an immune-inflammatory reaction.[91] Differential diagnoses include occult hemorrhage, septic shock, pulmonary thromboembolism, and anaphylaxis. An anesthetic accident is a

consideration if symptoms occur during cesarean surgery.[92]

The responsibility of the midwife present when symptoms occur is to summon emergency medical assistance, initiate cardio-pulmonary resuscitation if needed and to provide help within the response team. The woman with AFE will require intensive care including cardiopulmonary support and correction of coagulopathy. The mortality rate, once thought to approximate 100%, is now calculated to range from 11% to 44% using population-based studies.[93] The midwife will have an important role in providing support to the woman during recovery and assisting her transition to motherhood.

Shoulder Dystocia

Shoulder dystocia is defined as a birth requiring extra obstetric maneuvers after gentle downward traction on the fetal head has failed to release the shoulders.[94,95] Shoulder dystocia is believed to be caused by impaction of the fetal anterior shoulder on the symphysis pubis, or less commonly the fetal posterior shoulder on the sacral promontory. Although there is no standard description of shoulder dystocia, failure to deliver the fetal shoulders by the usual methods, prolonged head-to-body delivery time, and need for ancillary maneuvers are suggested criteria.[94] The true incidence of shoulder dystocia is not known due to variations in research design, lack of consensus on its definition, and differences in populations studied.[94,95] A recent review of literature from 1985–2012 found the incidence of shoulder dystocia overall is 1.4% in the United States.[94] The incidence in women who do not have diabetes is 0.6%, and that in women with diabetes is 1.9%.[94]

Risk Factors for Shoulder Dystocia

Antepartum risk factors for shoulder dystocia include macrosomia, pregestational and gestational diabetes, previous shoulder dystocia, maternal obesity, excessive weight gain during pregnancy, and multiparity.[96] The combination of two or more of these factors significantly increases the risk of shoulder dystocia.[96] Macrosomia is an especially significant risk factor. The incidence of shoulder dystocia is thought to rise with increasing fetal size, especially among infants born to women with diabetes.[95] The principal intrapartum risk factors for shoulder dystocia are a precipitous second stage of labor and operative vaginal birth. Rapid descent of the fetus during second-stage labor may not allow enough time for normal internal rotational maneuvers and compression of the shoulders toward the thorax, which results in impaction of the anterior shoulder behind the pubic bone. Midwives managing the second stage of labor for women with any of these risk factors should have a low threshold for requesting the immediate availability of the consulting obstetrician.

Prediction and Prevention Strategies

It is impossible to accurately predict shoulder dystocia. Known risk factors have a very low positive predictive value,[96] in part due to the lack of an accurate means of diagnosing macrosomia prenatally. Also, the great majority of macrosomic infants do not have shoulder

dystocia, and 48% of shoulder dystocias occur with infants who are not macrosomic. Cesarean birth prevents shoulder dystocia and most neonatal morbidity associated with an impacted shoulder. Nevertheless, planned cesarean birth for suspected macrosomia is not recommended due to the increased maternal morbidity, economic cost, and unreliable predictive accuracy of macrosomic infants, with two exceptions: (1) women with diabetes whose fetus has an estimated fetal weight of more than 4500 grams and (2) women without diabetes whose fetus has an estimated fetal weight of more than 5000 grams.[95]

Complications of Shoulder Dystocia

Even when managed appropriately, shoulder dystocia can result in neonatal injuries, such as a fractured humerus or clavicle and either temporary or permanent damage to the infant's brachial plexus (Erb's palsy). Prolonged fetal asphyxia during a difficult shoulder dystocia can also result in neonatal encephalopathy, seizures, and infant death. Maternal complications may include excessive blood loss (e.g., from postpartum hemorrhage) and perineal, vaginal, or rectal lacerations. Last-resort maneuvers such as cephalic replacement or abdominal rescue via cesarean birth significantly increase the risks for both maternal morbidity and perinatal mortality.

The neonatal consequences of shoulder dystocia are at the root of many medical lawsuits. For this reason, brachial plexus injury in particular has received considerable attention in the obstetric literature. This injury is thought to occur from forceful stretching or hyperextension of one side of the neck, which then results in avulsion or rupture of one or all of the brachial plexus nerves. Lateral traction applied to the infant's neck while attempting to deliver the anterior shoulder is the likely cause. While research has attempted to quantify the degree of force needed to cause a brachial plexus injury, this injury can also occur prior to birth and may be unavoidable in certain circumstances.[94]

Management of Shoulder Dystocia

The detailed management of shoulder dystocia can be found in Appendix 29A. For many years, the management of shoulder dystocia followed a specific protocol that began with external manipulation combined with maternal pushing efforts, which was often repeated several times before internal rotational maneuvers were attempted. Current evidence suggests shoulder dystocia management should focus on internal maneuvers such as rotation and delivery of the posterior arm, without maternal pushing efforts or placing any traction on the infant's neck.[97-100] This "hands-off" approach may decrease brachial plexus injury.[97-100]

Two recent commentaries argue in favor of a hands-off approach with all births.[100,101] These authors advocate expulsion of the shoulders during a normal birth by maternal effort only, waiting for the next contraction after birth of the head if necessary. It is theorized that this approach may allow for more complete internal rotation of the shoulders, possibly preventing some cases of shoulder dystocia.[100] It also avoids the lateral traction that may, in fact, be the cause of some cases of brachial plexus injury, even when the traction is not excessive.[101]

All professional organization recommendations agree that fundal pressure should never be

used, and that episiotomy should be performed only if extra room is needed for internal maneuvers.[95] ACOG recommends McRoberts' maneuver as a reasonable first step, while stating that there is no evidence of efficacy or safety that favors one release maneuver over another.[95] The Royal College of Obstetricians and Gynaecologists (RCOG) recommends against the use of any lateral traction to facilitate delivery of the shoulders, even in the absence of shoulder dystocia, recommending axial traction instead (i.e., in line with the fetal spine).[102] Maternal pushing efforts should not occur until the impacted shoulder is released.[102] The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends against maternal pushing efforts and any traction that causes severe neck traction.[103] Although there is not yet consensus on the issue of maternal pushing efforts and lateral traction to release an impacted shoulder, midwives should consider the theoretical concerns of these practices when managing a shoulder dystocia.

Another issue to consider is the use of the hands and knees position as a strategy to resolve a shoulder dystocia. Both RCOG and SOGC include this position in their shoulder dystocia algorithms after McRoberts' maneuver, rotational maneuvers, and delivery of the posterior arm, all with the mother lying on her back.[103,104] The rationale for this strategy is apparently assumed unfamiliarity with birth in this position, though midwives tend to have a greater familiarity with women giving birth on hands and knees. In addition, numerous anecdotal reports cite the woman's movement to this position itself relieving the impacted shoulder. If the woman is mobile, use of this strategy earlier than indicated in the RCOG and SOGC algorithms is reasonable.

Shoulder Dystocia Simulation

Given that the incidence of shoulder dystocia is relatively low and risk factors are not predictive, obtaining competency in management of this complication is challenging. While popular mnemonics are helpful memorization tools, evidence suggests simulation and team training are more likely to improve skills and confidence in managing a shoulder dystocia.[105-107] Research on simulation specifically related to shoulder dystocia has also shown that the use of high-fidelity manikins is preferred, especially when trying to learn and practice rotational maneuvers.[105-107] "High fidelity" refers to the ability of the equipment, the environment, and the learners to simulate and act as if the learning scenario is a real-life situation.[108]

Another advantage of simulation is the ability to train groups of learners to work together as a multidisciplinary team for resolving a specific clinical emergency, such as shoulder dystocia. At the end of the scenario, participants have an opportunity to debrief on the experience under the guidance of a skilled simulation coordinator. Teaching points are highlighted and the team is given constructive feedback related to the original learning objectives for the session. Studies have shown both improvements in confidence and skills when simulation is used for shoulder dystocia training.[105-107] Even though high-fidelity simulation centers may not be immediately available to all students and providers, the benefits of this type of learning experience in improving critical thinking and skills with shoulder dystocia management cannot be overstated.

Twin Gestation

In recent years, the incidence of twins and higher-order multifetal gestations has increased primarily due to the availability of assisted reproductive technologies. Currently, twin gestations occur in approximately 3% of all pregnancies in the United States and account for 17% of preterm births. Twins are associated with a sevenfold increased neonatal death rate compared to singleton gestations.[109] In addition, higher rates of congenital anomalies, fetal growth restriction, and maternal complications such as gestational hypertension, preeclampsia, and diabetes are found among women with multifetal gestations.[109] Lastly, intrapartum complications such as malpresentation, prolapsed umbilical cord, placental separation, and postpartum hemorrhage occur more frequently in twin gestations.[110]

When referring to twin gestations, it is critical to know the chronicity (one or two placentas) and the amnionicity (one or two amniotic sacs)—that is, the twins will be either dichorionic–diamniotic (di-di), monochorionic–diamniotic (mono-di), or monochorionic–monoamniotic (mono-mono). Chorionicity is explained further in the *Pregnancy-Related Conditions* chapter.

In most midwifery practice settings, women with a multifetal gestation require physician referral, especially if an intervening amniotic membrane has not been identified (mono-mono). For either mono-di or di-di twins, a collaborative management plan with the consulting physician can be considered (per practice guidelines) with strict criteria for referral of care. The woman will need ongoing surveillance for both maternal and fetal complications throughout the remainder of her pregnancy. An individualized plan of care regarding the optimal timing and mode of birth with the appropriate informed consent discussion will also be needed.

Mode of Birth

The mode of birth depends on the fetal presentation. Therefore, as the pregnancy progresses, the presentation and lie of each fetus will be carefully assessed and documented in the woman's prenatal record. Women with diamniotic twins in a vertex–vertex presentation are ideal candidates for a vaginal birth.[109,111] This option should be discussed with the woman well before the onset of labor, and the risks and benefits of vaginal birth versus elective cesarean section thoroughly reviewed. Current evidence does not show that cesarean birth improves perinatal outcomes in vertex–vertex presentations, and vaginal birth should be encouraged for all vertex–vertex presenting twins.[109,111]

Women at or beyond 32 weeks' gestation with diamniotic twins, with a vertex presentation of the first twin and a breech or transverse presentation of the second twin, are also candidates for vaginal birth if a provider skilled in internal podalic version and vaginal breech birth is present.[109,111] When the presenting fetus is breech, cesarean birth is recommended.[109,111]

Upon admission in labor, the presentation and lie of each fetus should be reassessed with ultrasound. The midwife should notify the consulting physician, and a collaborative management plan should be established if the woman desires a trial of labor. Intrapartum management guidelines for managing a woman with a twin gestation are found in **Appendix 29C**. Midwives may be required to assist a woman with a twin gestation or breech

presentation during birth if a physician is not able to be present when the birth occurs; thus, these skills are periodically reviewed as needed.

Fetal Malpresentations

The three fetal presentations possible are cephalic, shoulder, and breech. Cephalic presentations include vertex, sinciput (forehead), brow, and face, based on the degree of the flexion or extension of the fetal head.

- Vertex presentation: The occiput is the presenting part. If the fetus is in an occiput-anterior position, the smallest anterior-posterior and transverse diameters of the fetal head are presenting through the birth canal. This is the optimal position for vaginal birth. Variations include occiput posterior which is associated with prolonged labor, particularly prolonged second stage, and deep transverse arrest which is associated with arrest of dilation or arrest of descent in either the first or second stage of labor. In addition if the fetus is asynclitic, presenting diameters are enlarged and labor progress may be slower.
- Sinciput presentation: The fetal head is partially extended. The fetus in this position usually converts to vertex as the fetal head flexes toward the chin.
- Brow presentation: If the fetal head remains in the military position between full extension and full flexion, the brow becomes the presenting part. This presentation is the least common. The fetus in a brow presentation can convert to an occiput or face presentation but if the fetal head remains in this position, cesarean will be required because the mento-vertex diameter (13 cms) is the largest of the fetal head diameters and vaginal birth is precluded.
- Face presentation: If the fetal head is completely extended so the fetal occiput is in contact with the fetal back, the face will present. If the woman has an adequate pelvis, this fetus can rotate to a mentoanterior position and vaginal birth will ensue. If the fetus rotates to a mentoposterior position, cesarean section will be needed.

A shoulder presentation is possible for a fetus in a transverse lie. A cesarean birth is required if the fetus does not convert to a cephalic or breech presentation by the time labor starts.

Breech Birth

Even with careful assessment techniques, some women will present in labor with an undiagnosed breech presentation; thus, a breech presentation may be first diagnosed during a vaginal examination. Palpation of fetal small parts, usually the feet, or the buttocks may be encountered, although sometimes it is very difficult to distinguish the fleshy part of the breech from the soft-tissue caput on the fetal vertex. In some cases, the breech presentation is not discovered until the woman is well into active labor when fresh meconium stool is seen coming from the vagina. Once a breech presentation is confirmed, the woman should be informed and the consulting physician notified immediately. If the birth is imminent or a cesarean birth is not immediately available, the midwife should be prepared to perform a vaginal breech birth. **Appendix 29D** reviews the management steps for a vaginal breech birth. All midwives caring for laboring women should be thoroughly familiar with these techniques.

Prior to the late 1990s, vaginal breech birth was a common occurrence and an important component of obstetric training for both midwives and physicians. The publication of the Term Breech Trial in 2000, however, dramatically changed practice patterns regarding vaginal breech births.[112] This multicenter, randomized study originally reported that elective cesarean section for breech presentation significantly decreased perinatal morbidity and mortality. Almost immediately, women with a breech presentation were no longer given the option for vaginal birth. Closer examination of the definitions and methodology used in the Term Breech Trial has since challenged the reliability and validity of these findings.[113] Several protocol violations have been identified, and subsequent studies have reported conflicting results with regard to perinatal outcomes based on mode of birth for the fetus in a breech presentation.[112-115] In brief, current evidence suggests vaginal breech birth is associated with an increased risk of some adverse neonatal outcomes such as perinatal mortality and low Apgar scores, but studies completed to date have not had sufficient power to accurately identify the incidence of these outcomes. Maternal morbidity is higher in women who undergo cesarean section, and follow-up of children at age 2 years also reveals an increased incidence of medical problems within the cohort of children born via cesarean section.[115]

Unfortunately, these updated findings have failed to completely reverse the clinical changes brought about by the Term Breech Trial. The current medico-legal environment has continued to influence practice, with the result that women with a breech presentation today are still often advised to have an elective cesarean birth. More importantly, since the Term Breech Trial was published, expertise in vaginal breech birth and clinical learning opportunities have diminished. As a result, vaginal breech birth is now included in simulation training curricula along with other high-risk obstetric skills such as shoulder dystocia management. Midwives are encouraged to participate in these training experiences whenever possible.

Some women with a breech presentation will decline surgery or seek out a provider who will perform a planned vaginal breech birth. Current guidelines for these circumstances have been established, and institutions that can safely offer this service are encouraged to develop protocols for intrapartum management.[114] The option for planned vaginal breech birth is based on the availability (and willingness) of an obstetrician experienced in this mode of birth. A thorough shared decision-making discussion with the woman is also mandatory. Some sources

have outlined specific selection criteria shown to improve success rates, such as sonographically determined estimated fetal weight between 2500 and 4000 grams, frank or complete breech, no fetal anomalies, adequate maternal pelvis, adequate amniotic fluid, and flexion of the fetal head (documented by ultrasound).[114]

Special Clinical Situations

Birth is often thought of as the beginning of a person's life—but it can also be the end. Although birth is a joyous occasion for most women, stillbirth and the birth of a newborn with a critical illness or lethal anomaly are among the most profound traumas that a family can experience. These clinical scenarios can be traumatic for all involved.

Intrapartum Care of a Woman with a Stillbirth

The majority of women who are identified as having a stillbirth will opt for an in-hospital birth. The following discussion addresses this situation.

Hospital staff should be informed of the diagnosis before the woman's arrival and have a labor room arranged for her that will ensure privacy and liberal visitation from family members. Many labor and birth units have mechanisms in place that discreetly communicate a fetal demise (or lethal anomaly) to the entire staff (e.g., a special door magnet). It is especially important that the woman is not accidentally approached by a staff member who is unaware of her diagnosis and assumes she is a "normal" labor patient expecting a healthy newborn.

The midwife's role in the care of a woman with a stillbirth or a fetus with a lethal anomaly will vary according to individual practice guidelines and the specific clinical circumstances. A physician should be consulted to establish the most appropriate plan of care, which may in some cases require referral for medical management. The midwife's continued presence and availability, however, can provide emotional support and comfort for the woman and her family, especially in the immediate postpartum period. Midwives caring for women in these situations will have their own emotions and sadness to deal with. The priority is always to focus on the woman's immediate needs during labor and birth.

Once the woman is admitted, the midwife should thoroughly review the prenatal chart and all documentation of previous discussions regarding the proposed plan of care. A complete blood count and coagulation studies (especially platelets and fibrinogen) are obtained on admission to provide a baseline assessment of clotting factors due to the potential risk of disseminated intravascular coagulation (usually seen with prolonged fetal retention of . 2 weeks).[116,117] If an induction of labor is planned, a physician should be consulted to determine the most appropriate method of induction and cervical ripening. The specific agents and protocols used will depend on the woman's diagnosis, fetal gestational age, past obstetric history, and current Bishop's score.[116] This plan should be reviewed again with the woman and her family, with clear explanations of what to expect as labor and birth progress. The woman may need information repeated and should be given opportunities to express her feelings and ask questions. Every effort must be made to honor the woman's choices and requests.

Most labor and birth units have specific protocols and checklists in place for bereaved parents that include referrals to social services, the availability of a chaplain, assistance with burial plans, and collection of photographs, footprints, and other keepsakes from the baby after the birth has occurred. These services are offered to the woman at the appropriate times over the course of hospitalization. Religious and cultural choices are supported and respected (e.g., desire to baptize the infant).

The woman and her support persons will also be informed about the availability of detailed fetal evaluation after the birth. This evaluation includes a standard autopsy, collection of blood or tissue samples, and a pathology evaluation of the placenta and umbilical cord.[116] Less invasive options may also be available such as photographs, X-ray imaging, and ultrasonography.[116] It can be gently emphasized that this information may be useful to her and her family in planning future pregnancies. Tissue or amniotic fluid samples for fetal karyotype, in particular, may diagnose a syndrome or chromosomal abnormality without the results from a full autopsy.[116] If she declines autopsy or tissue sample collection, the placenta and umbilical cord should still be sent to pathology after the birth.

Parents may have difficulty making firm decisions, especially with regard to seeing or holding the infant at birth. If the woman has previously stated that she does not want to see the infant after the birth, the nursing staff should be prepared to take the infant to another location after the birth occurs. Women may change their minds about this point, however, and the midwife should remain open to all possibilities.

The birth itself is managed the same as with any other vaginal birth, except that there may be softening or overriding of the fetal skull bones or anomalies not previously identified. In addition, there is an increased risk of shoulder dystocia. Caution should be used when applying even gentle traction to any part of the fetus during the birth; instead, it is best to rely mostly on the woman's expulsive efforts. The umbilical cord should be clamped and cut as close to the abdomen as possible and the infant gently wrapped in a towel. The placenta should be delivered in the usual fashion and any lacerations repaired.

After the birth, the infant, umbilical cord, and placenta should be carefully examined for any recognizable abnormalities. Any deviations from normal (e.g., a true knot in the umbilical cord) should be shown to the woman and her partner. Sometimes seeing an obvious cause of death is reassuring for grieving families who are searching for answers. Unfortunately, the majority of intrauterine deaths cannot be attributed to a known cause, so it is important not to offer a potential diagnosis without clear evidence.

The woman and her family can be encouraged to view, touch, and hold the infant and allowed as much time as needed. Often photographs are taken and keepsakes (e.g., a lock of hair and footprints) are obtained and given to the parents. Once they are ready to say goodbye, the infant can be brought to the morgue per hospital policy.

Life-Threatening or Lethal Fetal Diagnosis

Due to improvements in diagnostic technology, more parents have advanced knowledge of a life-threatening fetal diagnosis prior to birth. In some cases, this early diagnosis may enable prenatal transfer of the woman to a tertiary center and consultation with neonatal specialists capable of interventions that will improve the infant's survival. In other cases, the woman and her partner have the task of deciding whether to continue the pregnancy to term. Depending on the gestational age at the time of diagnosis and individual state laws, elective termination of the pregnancy beyond the second trimester or a preterm induction of labor may not be an option. This section focuses on pregnant women with a known lethal fetal anomaly who present at full-term gestations either in spontaneous labor or for a planned induction.

In the majority of cases, the woman and her family will likely be receiving care from a multidisciplinary team that includes neonatology, maternal–fetal medicine, genetics specialists, and social services. In some settings, a perinatal palliative care plan has been established, and many of the decisions facing grieving parents during labor and birth have been discussed with the woman and her partner. Perinatal palliative care is an emerging field that moves beyond traditional bereavement support and is initiated at the time of diagnosis rather than during labor and birth.[118] This holistic approach incorporates the principles of bereavement care by integrating the woman's choices and understanding with realistic goals for care of the baby after birth, including perinatal hospice care. Ensuring quality of life, reducing pain and suffering, and honoring the infant's life and death are at the core of this framework.[118]

Once the woman is admitted to the labor unit, a collaborative plan of care is required with a consulting physician. Other care team providers (e.g., neonatology, pediatrics, chaplaincy) are notified of the impending birth. Depending on the type of anomaly, the gestational age, the expected perinatal outcome, and maternal medical conditions, physician management may be necessary.

The intrapartum management in this situation is similar to the care of a woman with a stillbirth. Regardless of the amount of prenatal counseling and support, the woman may exhibit a wide range of emotional responses during labor. All pain relief options should be available if requested. In addition, as second-stage labor nears, she may experience more difficulty coping and become quite conflicted about pushing. The birth represents facing the confirmation that the infant is going to die, and "holding on" subconsciously prevents this outcome from happening. Providing gentle encouragement, support, and patience will allow the woman to work through any emotional tethering and facilitate her sense of control over the situation.

If the neonatal team is planning to examine the newborn after birth, it may be less distracting for the woman to have them wait outside the room until after the birth occurs. Having a perinatal palliative care plan in place will facilitate the seamless transition from birth to end-of-life care.[118]

Conclusion

Complications during labor and birth can occur at any time, and knowledge of these conditions is essential for midwifery practice. Understanding the condition, its natural course, the effects on the woman and her fetus, and the degree of consultation, collaboration, or referral required are the basic competencies needed for all obstetric complications. In addition, because emergencies are unpredictable, management of the most common types will enable midwives to care for women safely. All women who experience a complication intrapartally will greatly benefit from the continuity, education, and support that a midwife provides.

APPENDIX

29A

Shoulder Dystocia

AMY MAROWITZ

The editors acknowledge Linda A. Hunter, who was the author of this appendix in the previous edition.

Shoulder dystocia is an obstetric emergency that most midwives will inevitably encounter in clinical practice. Management is focused on systematic steps that are designed to minimize adverse outcomes, especially injury to the infant's brachial plexus. This appendix reviews the key points and management steps required for safe intrapartum practice in the event of a shoulder dystocia.

Clinically, signs of an impending shoulder dystocia occur while the woman is pushing as the infant's head slowly extends and emerges over the perineum. Instead of fully extending, the vertex partially retracts back into the vagina, a phenomenon commonly referred to as the "turtle sign" (**Figure 29A-1**). Restitution and external rotation do not occur, as the infant's shoulders have not followed the normal cardinal movements through the pelvis and are impacted in an anterior–posterior position. In cases of maternal obesity, it may appear as if the "turtle sign" is occurring when there is simply excess maternal soft tissue that impedes the extension and rotation of the infant's head. Abducting the hips, called McRoberts' maneuver, causes the symphysis to shift up over the anterior shoulder of the newborn, which usually allows enough room for normal birth mechanisms to occur (**Figure 29A-2**).

Figure 29A-1 Turtle sign. Note that the infant's chin cannot be seen because the head has retracted into the vagina.

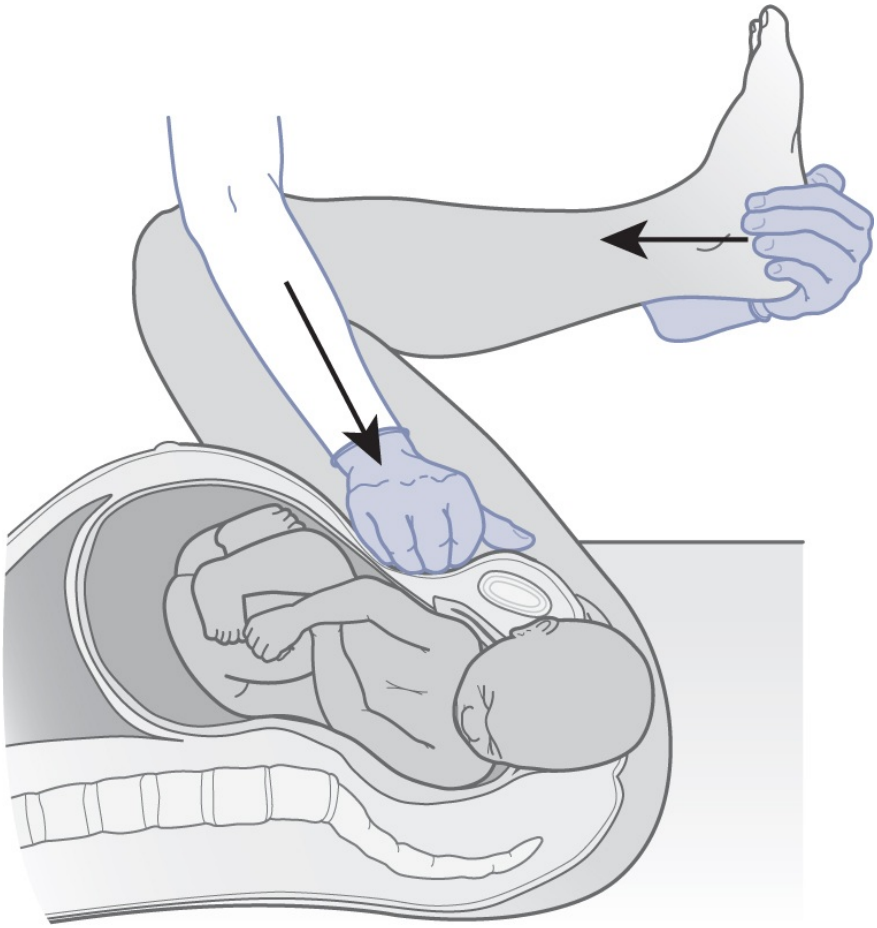

Figure 29A-2 McRoberts' maneuver and suprapubic pressure.

While accurate diagnosis of a shoulder dystocia is critical, it is equally important for the midwife to remain calm and fully assess the situation. After the head is delivered, waiting for the next contraction to allow for normal restitution and allowing the woman to push the infant out of the vagina unassisted may reduce the incidence of shoulder dystocia. If restitution and external rotation do not occur, it is equally important to first assess the location of the shoulders prior to initiating any maneuvers (other than repositioning the mother). Midwives who are attending births at home or in a birth center may need to enlist the assistance of the woman's partner and/or family if a shoulder dystocia is encountered. Even if the dystocia is resolved quickly, resuscitation assistance and ambulance transfer to the nearest hospital may still be needed for both the woman and her newborn.

After a shoulder dystocia occurs, a carefully written delivery note documenting the details of the birth and the sequence of events/maneuvers should be completed. Some institutions have specific delivery note templates or forms that are used following a shoulder dystocia. At a minimum, this note should include the position of the head at birth, which shoulder was anterior, time of the birth of the head, who was present or called, maneuvers that were done and in which order, time of the delivery of the body, newborn weight and Apgar scores, cord blood gas results if obtained, disposition of the newborn, and any motor deficit in the upper extremities noted on initial newborn examination; any maternal injuries should also be identified. In addition, using the term "traction" or trying to quantify the amount of force should

be avoided. From a medico-legal standpoint, it should be noted that fundal pressure was *not* used. The events should be explained clearly and simply with no attempts to editorialize or speculate.

Shoulder dystocia is a traumatizing event for all involved. It may be helpful for the midwife to organize a debriefing with the other staff and providers who were present as soon as possible to discuss what happened in a nonthreatening, supportive way. The midwife should also stay in close contact with the woman and her support persons. In the event of a serious shoulder dystocia, they may be facing devastating neonatal consequences and need ongoing support and follow-up. It is also essential that the midwife provides honest and accurate information to the woman regarding what happened during the birth without any blame or judgment.

Definitions of Shoulder Dystocia[1-4]

1. Impaction of the anterior shoulder behind the pubic bone
2. Impaction of the posterior shoulder on the sacral promontory
3. Prolonged head-to-body delivery time greater than 60 seconds
4. Need for ancillary maneuvers to deliver the shoulders

Incidence[1,2]

1. Varies in different studies due to variations in research design, lack of consensus on its definition, and differences in populations studied.
2. Contemporary review of literature: Incidence is approximately 1.4% of all births.
3. May be underreported due to variations in study design, definition, and population.
4. Incidence rises with increasing fetal weight.
5. Incidence is highest in women who have diabetes and a macrosomic fetus.

Risk Factors[5]

1. Prenatal risk factors
    a. Fetal macrosomia (more than 4000 grams)
    b. Maternal diabetes
    c. History of shoulder dystocia in a previous pregnancy
2. Intrapartum risk factors
    a. Precipitous second stage
        i. Rapid descent that does not allow enough time for normal rotational maneuvers
    b. Operative vaginal delivery (forceps or vacuum extraction)
    c. Prolonged second stage (increases the risk for operative delivery)

3. Associated risks (all of which increase incidence of macrosomia)
    a. Obesity
    b. Excessive weight gain
    c. Late term and post-term gestation

Key Points

1. Stay calm and clearly communicate to the woman and the team.
2. Do not panic and do not rush.
3. Be systematic and deliberate in moving through the procedures.
4. Keep hands off the infant's head as much as possible and minimize traction on the head.
5. These maneuvers are done when the woman is *not* pushing.
6. Do *not* let anyone perform suprapubic pressure until asked for by the person attending the birth.
7. Under *no* circumstances should anyone *ever* perform fundal pressure.
8. Try a maneuver once and then move on to another one; spend no more than 30 seconds on each maneuver.
9. Keep the team informed as each maneuver is performed.
10. Cut an episiotomy *only* if unable to get an entire hand into the vagina.
11. Start an intravenous line and obtain blood for a type and screen if this has not been done.
12. Continuously monitor the FHR and administer oxygen to the woman if needed.
13. Do not clamp or cut a nuchal cord during a shoulder dystocia; plan to deliver the infant with the somersault maneuver once the dystocia is resolved (see the *Hand Maneuvers for Birth* appendix in the *Second Stage of Labor and Birth* chapter).
14. Be prepared for a postpartum hemorrhage after the infant is born.
15. Be prepared for a full neonatal resuscitation. Cord blood gases should be sent if the shoulder dystocia was prolonged or if there is any sign of neonatal distress after the birth.
16. Neonatal asphyxia becomes a significant risk by 5 minutes. Rescue maneuvers (cephalic replacement or abdominal rescue) should be considered by 4 minutes. These will require transfer to the operating room and the availability of an obstetrician.

Management Steps

There is no clear superiority in terms of order of release maneuvers. Use of McRoberts' maneuver as a first step for women who give birth in a supine position is commonly recommended.[2-4] Steps 4, 5, 7, 8, 12, and 13 describe individual release maneuvers. The circumstances and midwife's judgment should guide the order of maneuvers when a shoulder dystocia occurs.

1. The moment that shoulder dystocia is suspected, have the woman *stop* pushing and

immediately assess the position of the fetal shoulders with a vaginal examination.

2. If the anterior shoulder is impacted, calmly and clearly state, "I have a shoulder dystocia."
3. Request help—additional nurses, the consulting physician, the neonatal team, and anesthesia should be called immediately.
4. Have the woman move to the edge of the bed and then into *McRoberts' position* (head down and knees/hips hyperflexed toward abdomen; **Figure 29A-3**). Hyperflexing the legs does not increase pelvic diameters but causes cephalic rotation of the symphysis so the symphysis slides up and over the anterior shoulder. Tell the woman not to push.

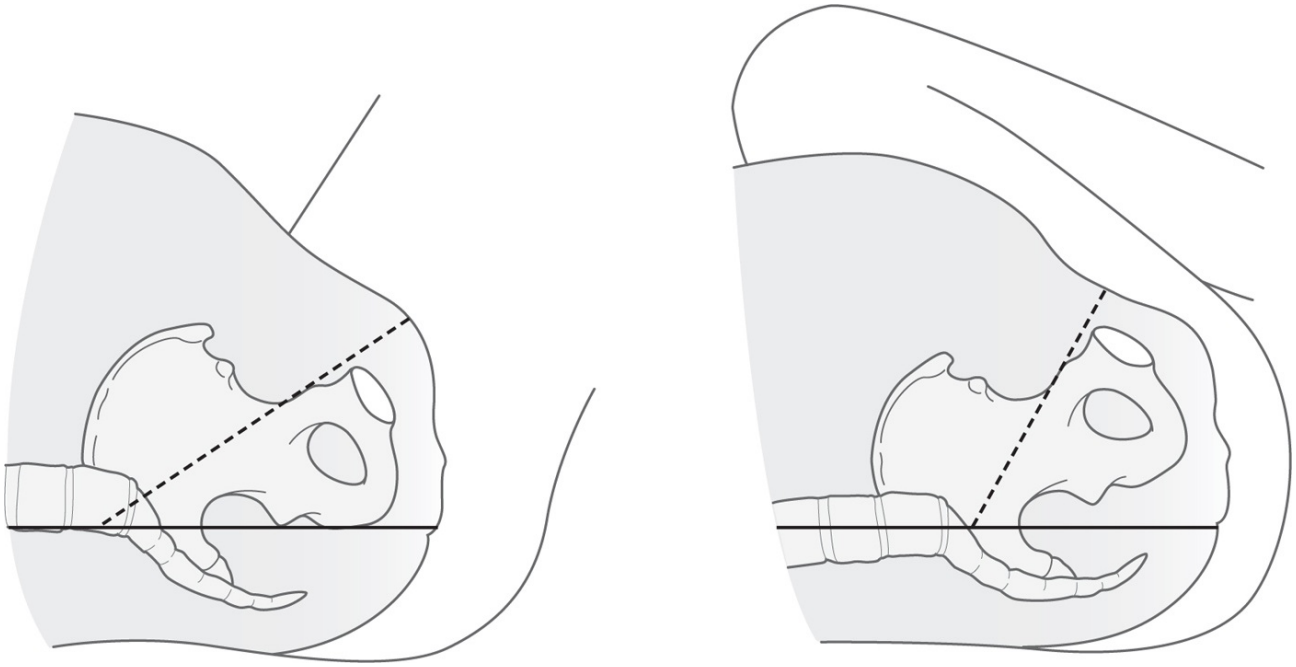

Figure 29A-3 Effect of McRoberts' maneuver on the symphysis. Notice that adduction of the legs toward the woman's abdomen moves the symphysis up so it slides over the fetal anterior shoulder.

5. Direct another person to perform *suprapubic pressure* at a slight angle in the direction you are trying to rotate the shoulder toward the fetal chest. Do this in between contractions first.
6. *The combination of McRoberts' maneuver and suprapubic pressure* will likely relieve the majority of shoulder dystocias. If it is not working, the fetus may be too large to fit in this alignment and will need rotational maneuvers.
7. *Rubin's maneuver*. Insert a hand (or as many fingers as possible) behind the anterior shoulder on the fetal back, and try to rotate the shoulder forward into an oblique position in the pelvis. This is also referred to as "collapsing the shoulders" and may help reduce the bisacromial shoulder diameter. The woman can attempt to push in coordination with your hand rotating the shoulder and the directed suprapubic pressure by an assistant. Use minimal and very gentle lateral traction (on the fetal shoulder—not the fetal head or neck). If this does not easily relieve the dystocia, repeated attempts will increase the force and the risk of brachial plexus injury and should not be continued.

8. *Delivery of the posterior arm.* Insert an entire hand in the posterior aspect of the vagina and follow the posterior arm to the infant's elbow. If the arm is extended, try to reach the forearm and bend the arm at the elbow until you can feel the infant's hand. Either grasp the hand or put gentle forward pressure on the elbow to sweep the arm across the chest and out of the vagina. There is an increased risk of humerus or clavicle fracture, but in the majority of cases, delivery of the posterior arm will relieve the dystocia. Because this maneuver is associated with the lowest risk of brachial plexus injury, some providers choose to try it before trying Rubin's maneuver.
9. Move gently, deliberately, and with purpose. Imagine you are inserting your hand into a circular can of potato chips or through a tight bangle bracelet. Continue to let the team know what you are doing (i.e., "I am going to try to deliver the posterior arm").
10. Cut an episiotomy *only* if more room is needed to insert your hand.
11. Continue to coach the woman not to push and keep her informed—her continued cooperation is critical.
12. *Gaskin maneuver*. Have the woman move onto her hands and knees. If the dystocia is not resolved with repositioning, attempt to deliver the posterior arm. If unsuccessful, rotational maneuvers can be attempted in this position or resumption of a supine McRoberts' position may be preferable
13. *Rotational maneuver.* With a hand firmly against either the posterior or anterior shoulder, push the shoulder clockwise or counterclockwise in an attempt to rotate it in a 180-degree arc. Continue to rotate the shoulders back and forth in whichever direction they will move until the impaction is dislodged and the infant is born. This maneuver may require both hands (one anterior and one posterior) pushing in opposite directions (**Figure 29A-4**).

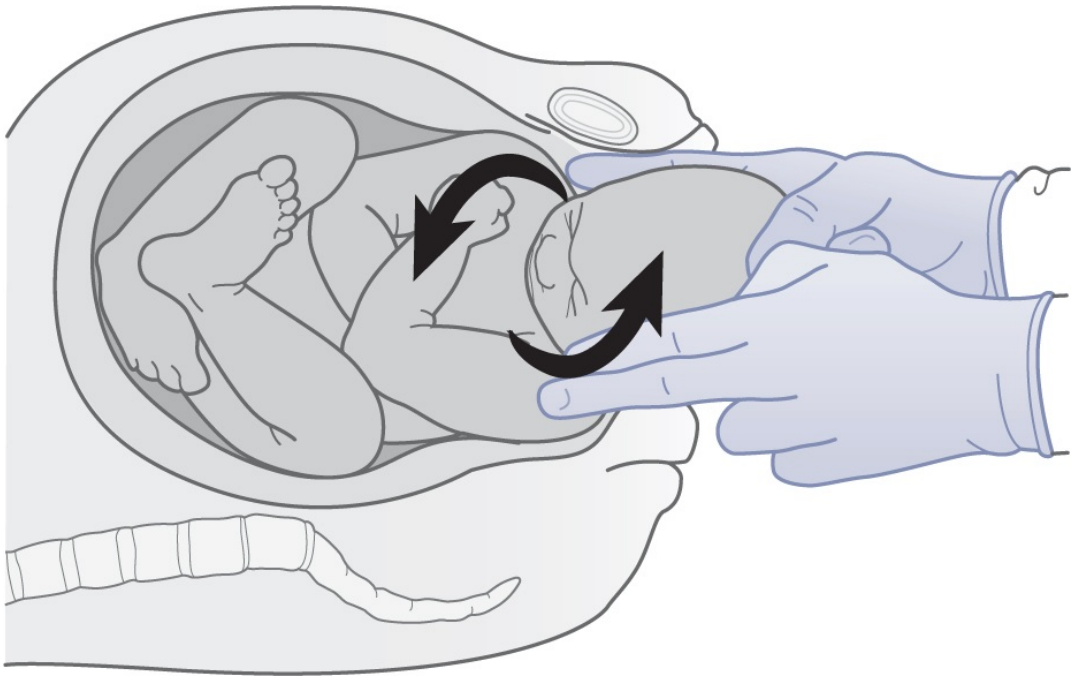

Figure 29A-4 Woods' screw (rotational) maneuver.

14. When the consulting physician or another provider enters the room, step aside and let that person try to facilitate the birth.
15. Intentional fracture of the clavicle may decrease the bisacromial diameter but may be difficult to perform in an emergent situation.
16. By 5 minutes, the risk of neonatal asphyxia starts to rise and rescue maneuvers must be considered. This will necessitate transfer to the physician and the availability of anesthesia and a full operating room team.
17. *Rescue maneuvers* include cephalic replacement (Zavanelli maneuver) or abdominal rescue, which both require a full operating room team and a physician capable of performing a cesarean delivery.

Emergency Interventions for Umbilical Cord Prolapse

AMY MAROWITZ

The editors acknowledge Linda A. Hunter, who was the author of this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

An overt umbilical cord prolapse is an obstetric emergency that will require the woman to undergo an immediate cesarean section. Often the first sign of a cord prolapse is a sudden fetal bradycardia or recurrent variable decelerations that rapidly get more severe. Management of this acute situation requires prompt action on the part of the midwife in recognizing the prolapse and performing the appropriate lifesaving interventions while an operating room team and the consulting physician are mobilized. **Figure 29B-1** depicts the types of umbilical cord prolapse.

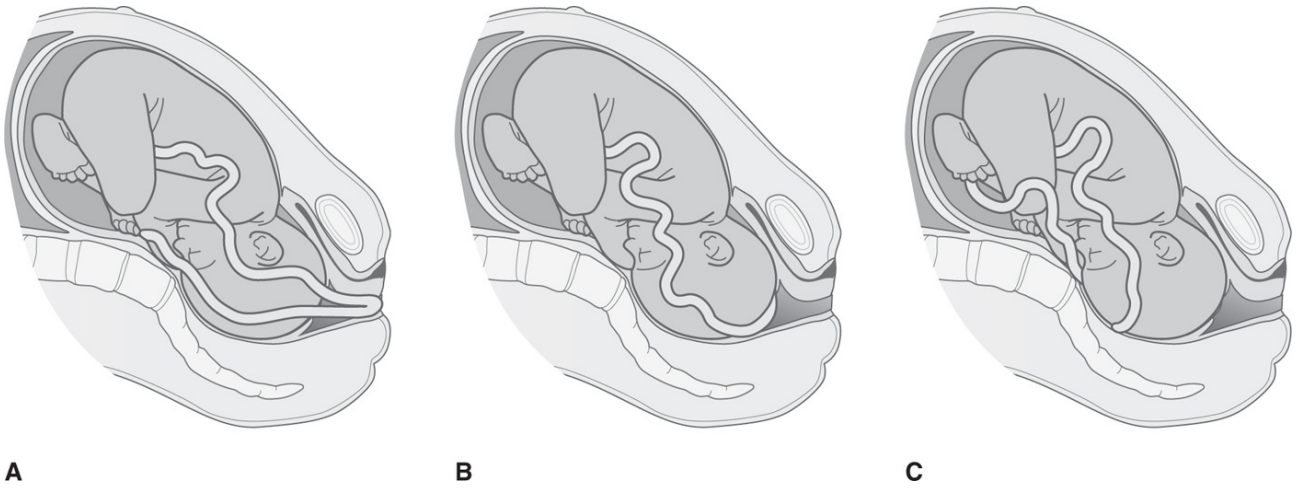

Figure 29B-1 Umbilical cord prolapse. **A.** Complete cord prolapse. **B.** Cord prolapsed in front of the fetal head. **C.** Occult (hidden) prolapse.

Definitions

1. *Overt:* The cord slips completely out of the cervix and is protruding in the vagina.
2. *Occult:* The cord is compressed alongside the presenting part in the lower uterine segment or inner cervix.
   a. Maternal repositioning or gentle upward pressure on the fetal head during a cervical examination can relieve an occult cord prolapse.
   b. If fetal heart rate (FHR) decelerations are present, intrauterine resuscitation measures should be initiated (see the *Fetal Assessment During Labor* chapter).
3. *Funic:* The cord is palpable in front of the presenting part.
   a. A funic presentation requires consultation with the collaborating physician to develop the most appropriate management plan.

Risk Factors

1. Prematurity
2. Multifetal gestation
3. Multiparity
4. Polyhydramnios
5. Fetal malpresentation
6. Rupture of membranes: intentional or spontaneous with an unengaged head

Management Steps

1. Call for help immediately and do not leave the woman.
2. Clearly state, “I have a prolapsed umbilical cord.”
3. Direct others to page a physician and notify the operating room team.
4. Inform the woman of what is happening and tell her she will need an emergency cesarean section.
5. Reposition the woman in the bed, tipped on her side (lateral Sims), or place her in knee–chest position.
6. Do *not* attempt to replace the cord in the uterus.
7. Put a sterile glove on and get into or on the bed, insert a hand into the vagina and firmly push up on the presenting part to relieve any compression on the cord. *Do not remove your hand or let up on the presenting part*.
8. Monitor the FHR continuously.
9. Administer oxygen and an intravenous fluid bolus.
10. Be prepared to accompany the woman into the operating room in this position riding on the bed.
11. The operating room staff will place the sterile drapes over you, and the physician will

let you know when the newborn is safely out of harm's way and you can remove your hand.

29C

Intrapartum Management of Twin Gestation

AMY MAROWITZ

The editors acknowledge Linda A. Hunter, who was the author of this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

Midwifery management of a planned twin birth should always occur in a hospital in close collaboration with a physician capable of performing a cesarean section. Many institutions require vaginal delivery of twins to occur in the operating room with anesthesia and an operating room team on standby. The neonatal (or pediatric) team should also be notified as soon as possible of a twin labor admission to ensure the presence of adequate nursing staff and personnel capable of full neonatal resuscitation of both newborns. Regardless of how the fetuses were identified during pregnancy, the first twin to deliver is referred to as "Baby A" and the second twin is "Baby B."

Incidence

1. 3% of all births
2. 40% will be vertex–vertex at onset of labor[1]

Types of Twins[1]

1. Monochorionic–monoamniotic (mono-mono)
   a. Requires referral for medical management
   b. Delivery by cesarean section typically at 32 weeks[1]
2. Monochorionic–diamniotic (mono-di)

3. Dichorionic–diamnionic (di-di)

Risks Associated with Twin Deliveries[1]

1. Preterm birth
2. Malpresentation
3. Prolapsed umbilical cord
4. Placental separation (especially with Twin B)
5. Postpartum hemorrhage
6. Preeclampsia
7. Placenta previa

Intrapartum Management Guidelines for Twin Gestations

1. Upon arrival in labor, the presentation and lie of each fetus should be reassessed with ultrasound.
2. These findings should be reviewed with the consulting physician to determine whether the planned vaginal delivery is still an option. This plan should be shared with the woman and her informed consent obtained.
3. The woman should have an intravenous line inserted with blood drawn for a blood type, antibody screen, and cross-match.
4. Management of labor pain is no different for twins, including use of epidural anesthesia if the woman desires. Epidural analgesia is recommended in many institutions as it can provide anesthesia for an emergency cesarean section if needed.
5. Continuous fetal monitoring of both fetuses is required throughout labor with an electronic fetal monitor that can record both heart rates simultaneously. A fetal scalp electrode should be inserted on Baby A only if medically indicated.
6. The consulting physician should be in the hospital and present in the room during the births. It is generally recommended that the births occur in an operating room as there is a significant risk of needing an emergency cesarean section for Baby B.
7. The management of Baby A's birth is no different than a singleton gestation. An episiotomy should be done only if medically indicated.
8. The umbilical cord from Baby A should be clamped and marked so that it is clear that this cord is from Baby A. For example, use one extra clamp for Baby A and two extra clamps for Baby B.
9. After the birth of Baby A, Baby B's position and presentation should be immediately assessed with ultrasound and the woman's cervix checked for dilation and station of the presenting part.
10. Baby B's fetal heart rate should be monitored continuously, as this is the period of risk

for umbilical cord prolapse.

11. If Baby B is presenting vertex, care should be taken when rupturing the membranes to avoid a prolapsed umbilical cord. Do not rupture the membranes if Baby B is unengaged.
12. If Baby B is not vertex, the physician should take over the management, especially if a breech extraction is anticipated.
13. A postpartum hemorrhage should be anticipated and the appropriate uterotonic medications and/or blood products should be immediately available.
14. The umbilical cords should be carefully marked to differentiate Baby A from Baby B and the placenta(s) sent to pathology.

Breech Birth

AMY MAROWITZ

The editors acknowledge Linda A. Hunter, who was the author of this appendix in the previous edition.

© hakkiarslan/iStock/Getty Images Plus/Getty

As discussed in the chapter, there may be circumstances when a woman with a known breech presentation is planning a vaginal delivery. Planned vaginal breech births should always take place within a hospital setting under the primary management of an obstetrician. Midwives in clinical practice are more likely to encounter a woman in advanced labor with a previously unknown breech presentation. While every attempt should be made to mobilize a team to perform a cesarean section, if the birth is imminent, it will occur vaginally. This appendix reviews the management techniques for a breech birth, and midwives are encouraged to periodically review these steps. As with other obstetric emergencies, participation in vaginal breech simulation drills has been shown to improve provider confidence and team communication. If available in their practice settings, midwives are encouraged to participate in these types of training experiences.

Incidence of Breech Presentation

Of all pregnancies, 3% to 4% at term.[1]

Types of Breech Presentations[1]

See **Figure 29D-1**.

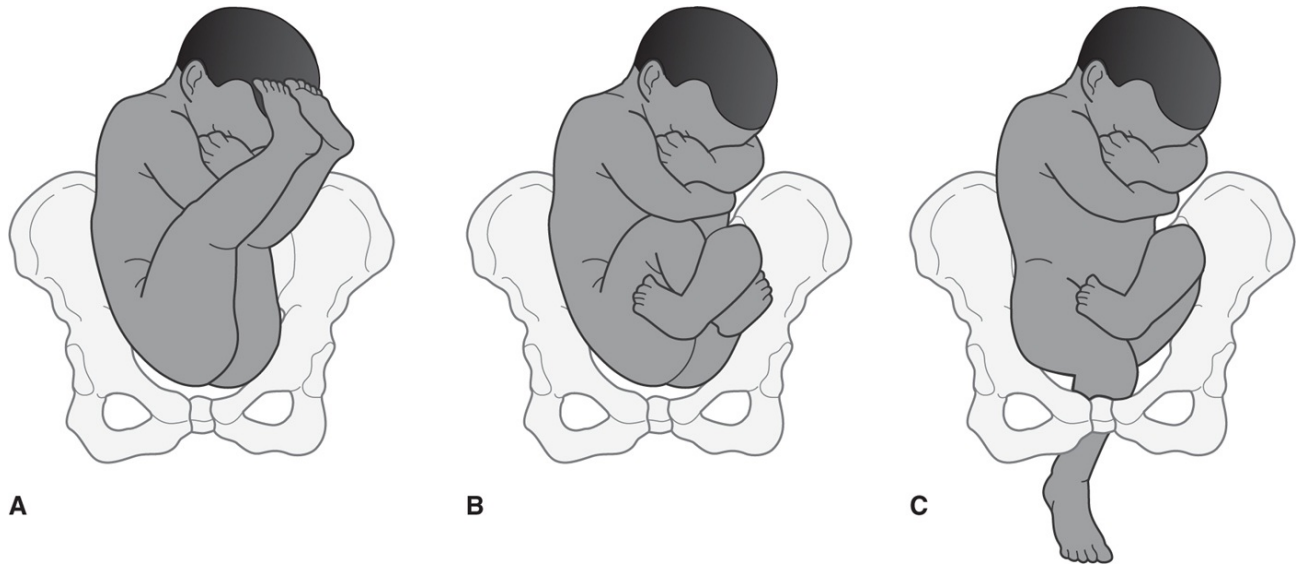

Figure 29D-1 Types of breech presentation. **A.** Frank breech. **B.** Complete breech. **C.** Footling (incomplete) breech.

1. *Frank breech (50–70%).* The lower extremities are flexed at the hips, with the legs extended and the feet near the infant's head ("pike" position). The presenting part is the infant's buttocks.
2. *Complete breech (5–10%).* Both the hips and knees are flexed, with both feet above the infant's buttocks ("cannonball" position). The presenting part is the infant's buttocks.
3. *Footling breech (10–30%).* One or both feet extend below the infant's buttocks and present in the vagina. This can be either a single or double footling presentation. A single footling is sometimes referred to as an "incomplete breech."

Predisposing Factors[2]

1. Preterm gestation
2. Multifetal gestation
3. Multiparity with lax uterine tone
4. Polyhydramnios
5. Oligohydramnios
6. Uterine anomalies (bicornuate uterus)
7. Uterine fibroids (especially in the lower uterine segment)
8. Placenta previa
9. Fetal anomalies (hydrocephaly, aneuploidy, nuchal masses)

Factors That May Improve the Success of Vaginal Breech Birth[3,4]

1. Average-size fetus (2500–3800 grams) with no known anomalies
2. Proven adequate pelvis
3. Frank or complete breech
4. Documentation of fetal head flexion (by ultrasound)
5. Spontaneous labor with normal progress
6. Easy spontaneous delivery of the buttocks and thighs

Key Points

1. Leopold's maneuvers are an important assessment tool but may be unreliable in determining presentation during active labor.
2. When performing a cervical examination on a woman in labor, palpation of the fetal skull sutures confirms a vertex presentation.
3. *Any* suspicion for breech presentation should always be confirmed with ultrasound.
4. In out-of-hospital sites, the midwife must rely on Leopold's maneuvers and a careful vaginal examination to palpate the fetal skull sutures. There should be no hesitation to transfer the woman to a hospital if a breech presentation is suspected. The midwife should also call 911 for additional help and notify the consulting physician, especially if the woman refuses transfer or the birth is imminent.
5. The infant's sacrum is the denominator (anatomic landmark for determining the position in the pelvis).
6. When a breech birth is imminent, the midwife should request the assistance of any available obstetrician (or a more experienced midwife if a physician is not available). The neonatal or pediatric team should also be called and staff prepared for full infant resuscitation. Anesthesia and an operating room team should be on standby in the event that surgical intervention is needed.
7. During the birth, the infant may pass thick meconium stool from compression of the breech in the vagina. This is often the first indication during labor of a "missed breech" presentation.
8. The fetal heart rate should be monitored continuously. The woman should also have an intravenous line inserted if possible and should be given oxygen if any signs of fetal acidemia are present.
9. The key management steps in a breech birth require a "hands-off" approach until the breech is delivered to the level of the umbilicus and considerable patience to allow for spontaneous progression of the normal cardinal movements. The woman should be allowed to push and her progress monitored closely.
10. If the woman has any contraindications to a vaginal breech birth, transfer to a hospital or operating room and preparation for a cesarean section is indicated. If contraindications are present, the midwife should assist with a vaginal birth only if the birth occurs before a cesarean section can be facilitated.

Cardinal Movements and Management Techniques for a Breech Birth

1. Descent occurs throughout and is facilitated by maternal pushing efforts.
2. Engagement of the hips usually takes place when the infant's bitrochanteric diameter (the distance between the outer points of the hips) enters the oblique diameter of the maternal pelvis. The position will then be either right sacrum anterior (RSA) or left sacrum anterior (LSA).
3. The anterior hip usually descends more rapidly than the posterior hip.
4. As resistance from the pelvic floor is encountered, internal rotation of 45 degrees will occur and the anterior hip will pass under the pubic bone. The bitrochanteric diameter of the hips is now in the anterior–posterior diameter of the woman's pelvis in either a right sacrum transverse (RST) or left sacrum transverse (LST) position.
5. As descent continues, the anterior hip provides a pivot for the posterior hip, which usually crosses the perineum first. Delivery of the anterior hip will follow through lateral flexion of the spine.
6. Until this point in time, the woman should be allowed to push as needed and descent of the breech observed closely. Resist the temptation to pull the buttocks out and allow the maternal pushing efforts to continue as in any normally progressing second stage. If the infant is born too quickly, the head may not have time to flex, which is necessary for birth of the head.
7. Once the buttocks are born and the umbilicus is visible at the perineum, the legs should be gently released one at a time through the vaginal opening. This should be done in between pushing efforts by following the thigh to the knee and sweeping the flexed leg across the infant's abdomen.
8. If the infant is in a frank breech presentation and the full extension of the legs has hindered descent, *Pinard's maneuver* can be used to "break up the breech" (**Figure 29D-2**). Insert either the right or left hand (depending on the sacrum's position) and follow the thigh to the popliteal fossa behind the knee. The thumb should be on the anterior side of the thigh. Gently press on the popliteal fossa and move the leg laterally away from the midline. This will cause the leg to flex at the knee, thereby bringing the foot down to where it can be grasped. Bring the leg down and out of the vagina by drawing it across the infant's abdomen in its natural range of motion. Repeat the maneuver for the other leg if needed.

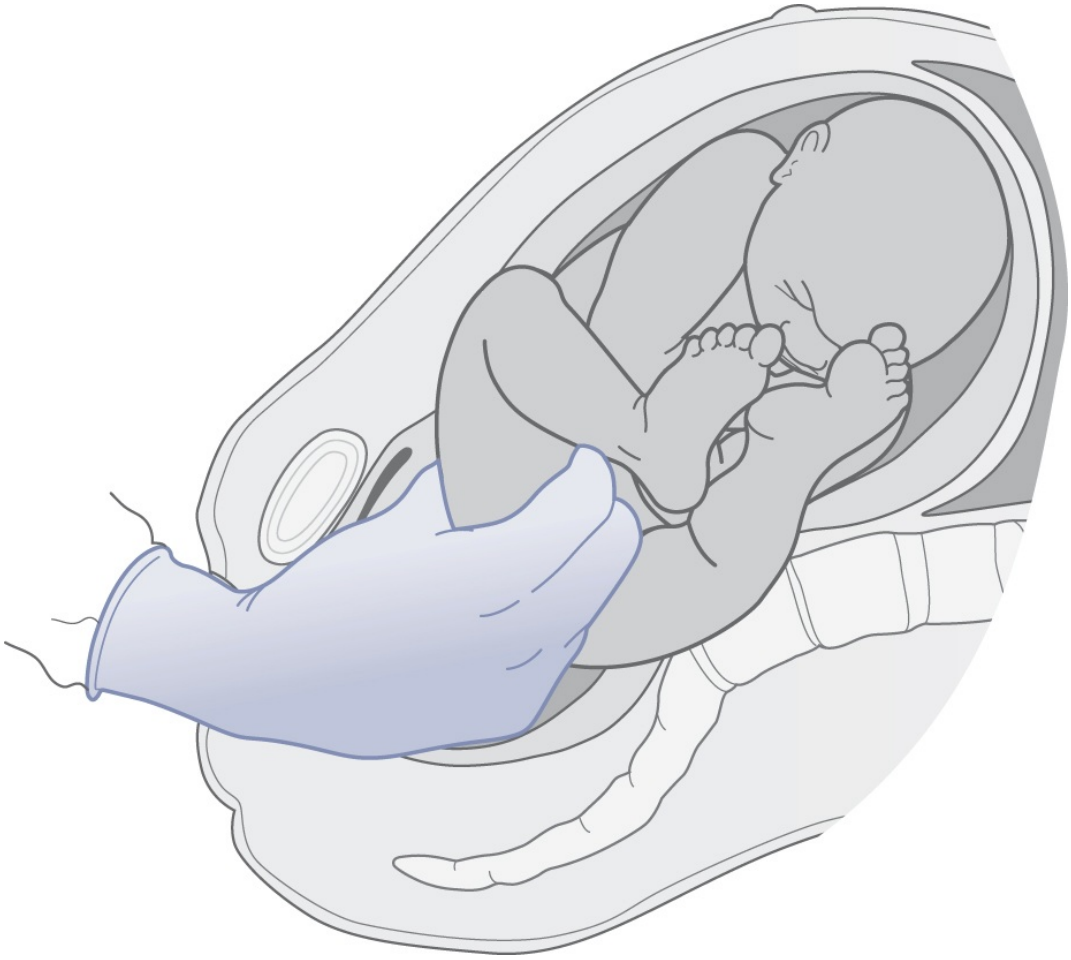

Figure 29D-2 Pinard's maneuver.

9. After the trunk, legs, and feet are delivered, external rotation will occur, aligning the infant's back into a sacrum anterior position. This will cause the shoulders to rotate internally into the oblique diameter of the maternal pelvis and pass under the pubic bone.
10. The remainder of the birth should occur within the next 3 to 5 minutes to avoid hypoxia from compression of the umbilical cord. A generous loop of the umbilical cord can be pulled down to prevent stress at the umbilical insertion site.
11. Wrap a warm towel around the infant's lower body just below the umbilicus. This will keep the infant warm and provide a nonslippery hold on the hips.
12. To facilitate birth of the shoulders, grasp the hips by placing the thumbs on the sacrum and the fingers on the corresponding iliac crests (**Figure 29D-3**). Avoid any pressure on the soft-tissue areas of the abdomen or flank.

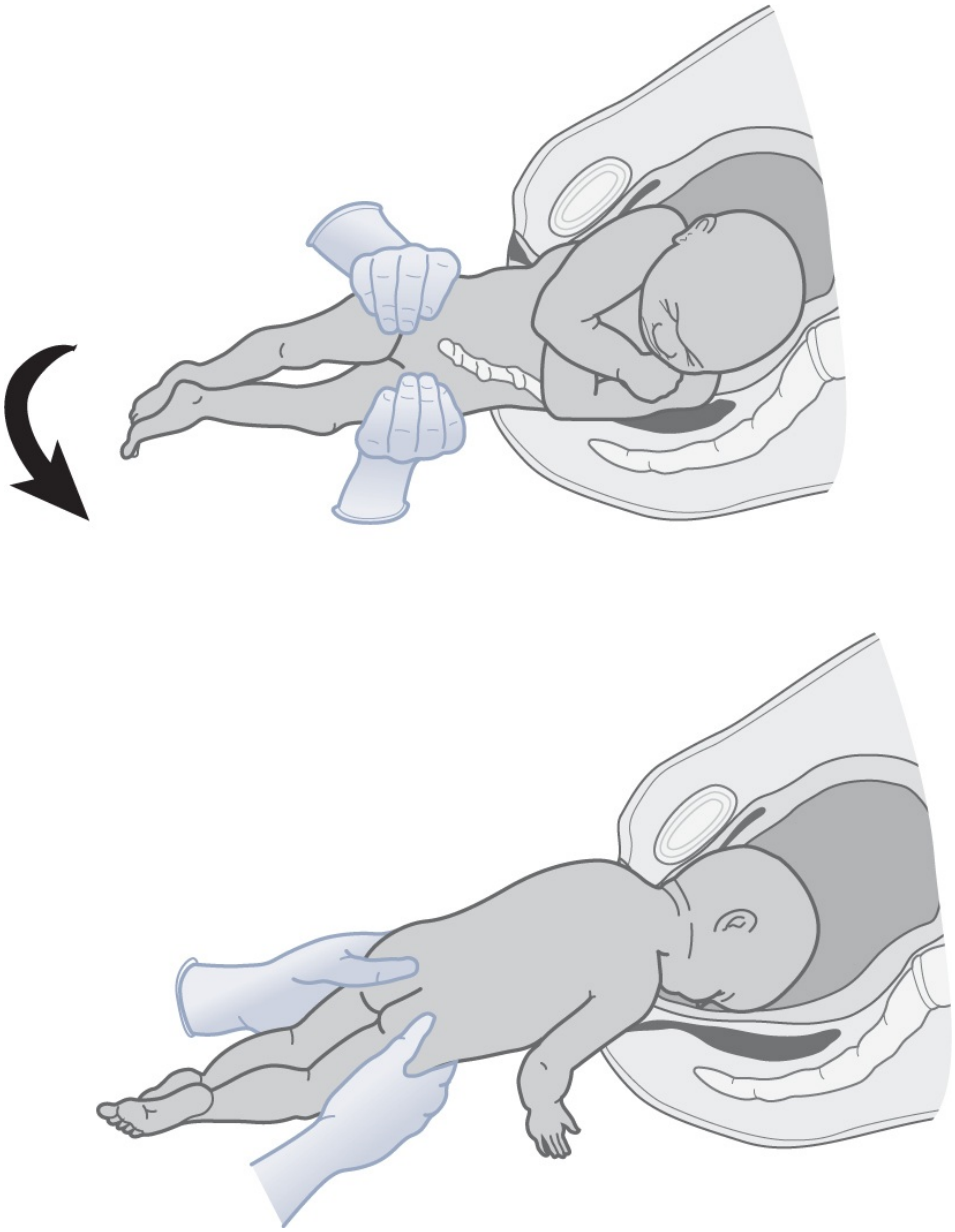

Figure 29D-3 The midwife's hands placed on the infant's lower body with thumbs over the sacral iliac joint.

13. Provide downward and outward traction on the body with coordinated pushing from the mother, and gently rotate the infant to either an RST or LST position (**Figure 29D-4**).

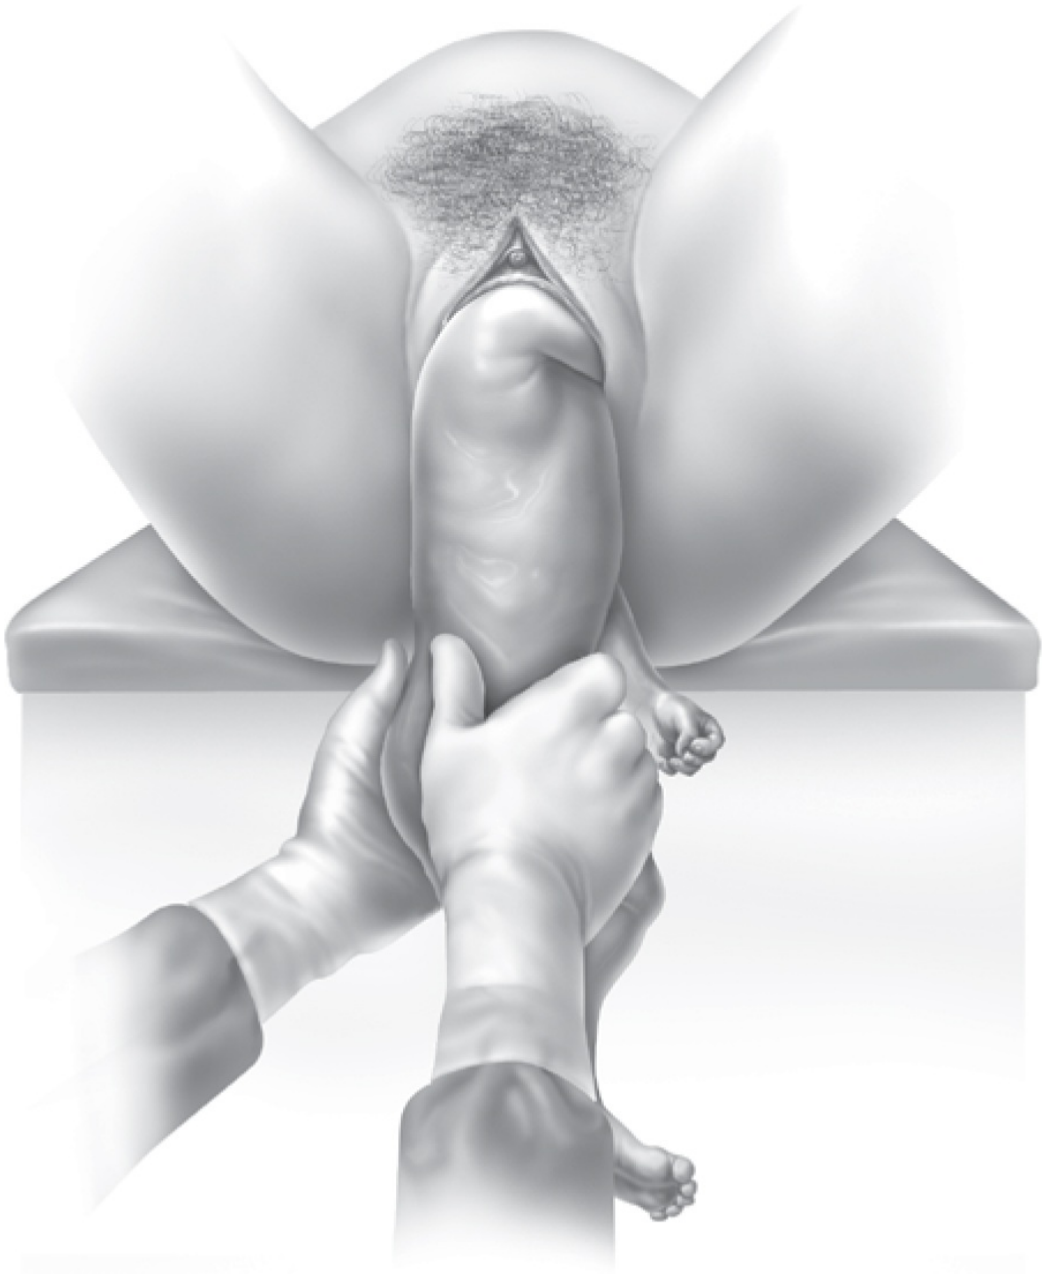

Figure 29D-4 Birth of the anterior shoulder by downward traction. Note the placement of the midwife's hands on the infant's hips.

14. Continue downward traction with maternal pushing efforts until both the scapula and the axilla of the anterior shoulder are visible.
15. *Delivery of shoulders and arms*. There are different techniques for delivery of the shoulders and arms, and it does not matter which shoulder is delivered first. Typically, the anterior shoulder will appear as a result of the downward traction placed on the body. Once the axilla is visible, the arm can then be delivered by reaching in to the elbow and sweeping the arm up across the chest. Once the anterior arm is out, the infant should be rotated 180 degrees, keeping the back up. This will bring the posterior scapula and axilla into view anteriorly, and this arm can be delivered in the same manner.

16. *Delivery of the posterior arm.* If the anterior shoulder does not appear with downward traction, the posterior arm can be delivered first. Grasp the feet securely in one hand and lift the body up and over toward the abdominal side until the scapula and axilla are visible posteriorly at the perineum. Insert the other hand along the upper arm to the elbow and sweep the arm across the chest. Now the infant can be either repositioned with downward traction again or rotated until the anterior shoulder and axilla are in view (**Figure 29D-5**).

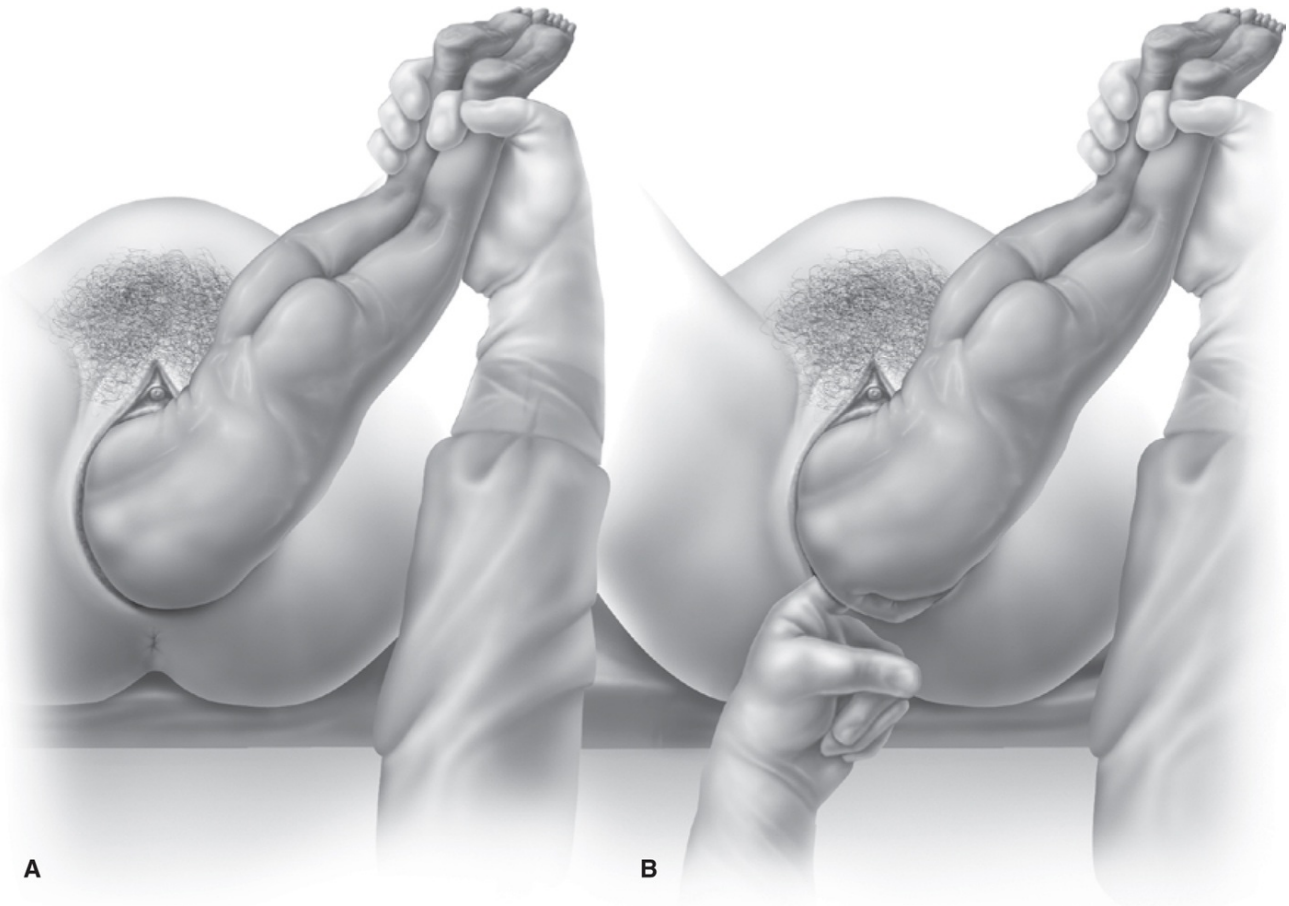

Figure 29D-5 Delivery of the posterior arm. **A.** Birth of the posterior shoulder by upward traction. **B.** Freeing the posterior arm.

17. Engagement of the head usually occurs in one of the oblique pelvic diameters. Internal rotation is facilitated by delivery of the shoulders; once the arms are released, the head is generally in an occiput anterior position, with the back of the neck visible at the vaginal introitus.
18. It is very important *not* to let the head rotate to the occiput posterior position, as any traction on the body will cause extension of the head and increase the chances of entrapment.
19. Delivery of the head is best accomplished using the *Mauriceau–Smellie–Veit maneuver* (**Figure 29D-6**). There are several variations of this maneuver, in which the hand is inserted posteriorly into the vagina and the fingers are positioned carefully in and/or around the baby's mouth to facilitate flexion of the head. Most commonly, the index and

middle fingers are placed on either side of the nose on the maxilla and downward pressure is applied to maintain flexion of the head. Extreme care must be taken to avoid any pressure on the lower jaw or accidentally inserting the fingers into the orbit of the eyes. Although insertion of a finger into the infant's mouth is sometimes described as part of this maneuver, this modification could cause serious damage to the tongue and surrounding tissues.

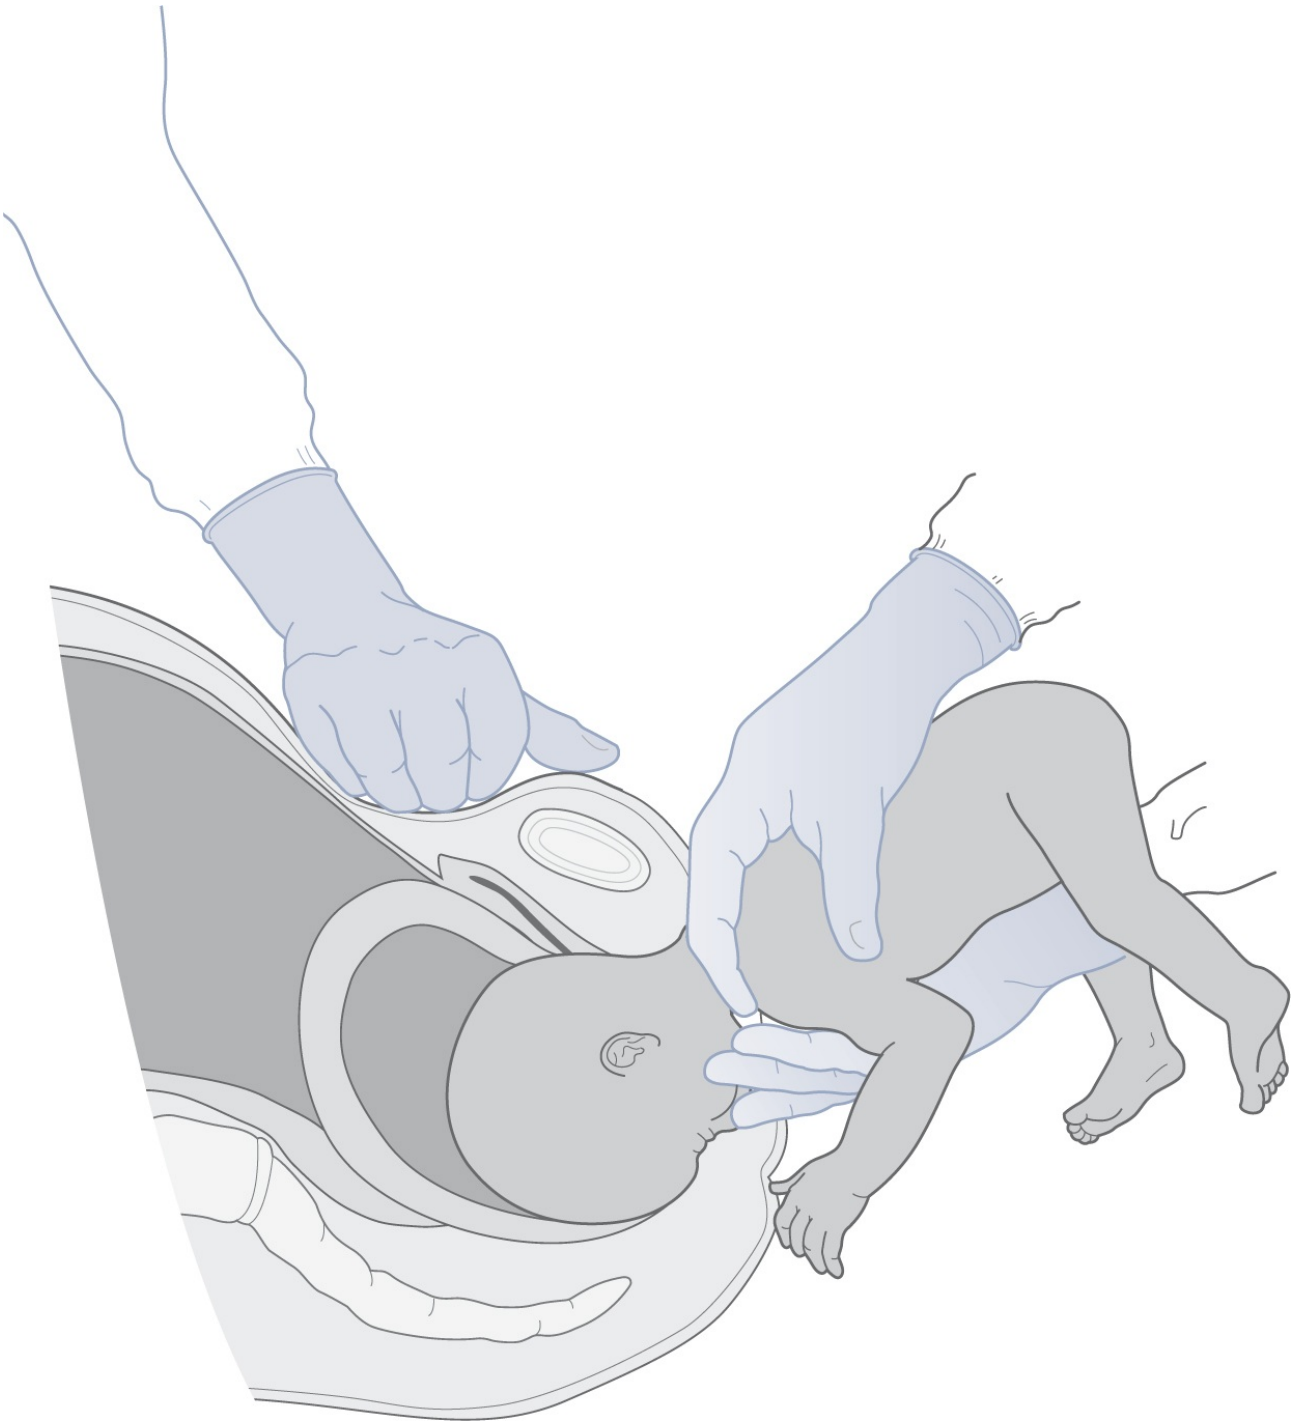

Figure 29D-6 Mauriceau–Smellie–Veit maneuver with suprapubic pressure.

20. Once the fingers of the posterior hand are in place on the maxilla, rest the infant's body

astride the length of the arm. Place the other hand on top of the infant and hook the index and middle fingers of this hand onto the shoulders on each side of the infant's neck. The fingers can also be placed along the occiput to splint the infant's head between the hands to prevent any extension of the neck and head.

21. An assistant should be directed to perform suprapubic pressure to maintain flexion of the head during this part of the birth.
22. Continue to apply downward traction with the infant sandwiched between the arms/hands until the hairline is visible under the symphysis pubis. Take care to avoid pressure on the brachial plexus.
23. Once the hairline is visible, apply upward traction while elevating the body of the baby. Following the curve of Carus, the chin, face, brow, anterior fontanelle, and the remainder of the head are delivered in sequence across the perineum.

CHAPTER

30

Third Stage of Labor

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

The birth of a child is exciting and the pinnacle of an intense and emotional period for the birthing woman and her family. However, the time immediately following the birth is also a critical one for both the woman and her newborn. The expulsion of the placenta and physiologic stabilization immediately following this event represent a period of great vulnerability. Postpartum hemorrhage (PPH) is one of the leading causes of childbirth-related maternal morbidity and mortality, both worldwide and in the United States; when it occurs, it most often does so during the third or fourth stage of labor.[1] Moreover, the first hour after birth is a "sensitive period" psychologically and physiologically, wherein continuous contact potentially has significant benefits for both the woman and her infant.[2] This chapter reviews the third stage of labor, methods for promoting normal physiologic adaptation, maternal complications that can occur during this time period, and management strategies for complications of the third stage.

Definitions

The third stage of labor is defined as the period following the birth of the newborn through the expulsion of the placenta. A duration of longer than 30 minutes without placental expulsion is the conventionally accepted criterion for the diagnosis of *prolonged third stage of labor*, which is also known as *retained placenta*. Retained placenta is associated with an increased risk for hemorrhage and complications that are partially related to the anesthesia used when the placenta must be manually removed.[3-6]

Physiology of the Third Stage of Labor

Duration of the Third Stage

The length of time for the third stage of labor to be completed is usually within 10 minutes.[7] Based on a review of more than 12,000 births, only 3% of third stages have a duration that is longer than 30 minutes.[5] The duration of the third stage of labor is commonly longer in preterm gestations compared to term gestations.[8] Although the outer limit of normalcy has not been conclusively determined for any gestational age, the risk of complications increases with increasing duration of the third stage at all gestations.[5-7] A study of more than 45,000 births found that following a term gestation birth, 90% of placentas will be expelled spontaneously within 15 minutes and 97.8% will be expelled within 30 minutes.[6]

In a setting in which uterotonic medications were routinely administered during the third stage of labor, researchers reported that the mean duration of the third stage was 5.6 minutes and the 99th percentile was 28 minutes.[5] In this analysis, the risk for postpartum hemorrhage was significantly increased (adjusted odds ratio [aOR] 1.82; 95% confidence interval [CI], 1.43–3.21; 13.2% vs 8.3%) when the duration of the third stage was greater than 20 minutes.[5] Although some research suggests the diagnosis of retained placenta should be applied when the third stage lasts 20 minutes or more,[5,6] 30 minutes without placental expulsion continues to be the standard definition for the prolonged third stage or retained placenta. While most settings in the United States initiate intervention after 30 minutes, the World Health Organization (WHO) recommends that, in the absence of bleeding, intervention not be initiated until 60 minutes after birth if the placenta has not delivered.[9]

Placental Separation

Contraction frequency and intensity in the third stage of labor are similar to the corresponding measures during the second stage of labor,[8,10] although the intensity of the contractions often is felt minimally, if at all by the woman, especially in comparison to the sensations associated with contractions immediately before the birth of the neonate. These post-birth contractions constrict the blood vessels that supply the placenta, thereby causing hemostasis. Placental separation is the result of an abrupt decrease in size of the uterine cavity following birth of the neonate. As the uterus contracts, the placental implantation surface area decreases without a corresponding change in the placental size. This sudden disproportion between the area of implantation and placental size causes the placenta to buckle and separate from the decidua.

After the placenta separates, it descends through the lower uterine segment and into the upper vaginal vault, causing clinical signs of placental separation. **Table 30-1** lists the common signs of placental separation. During placental separation, women who do not have analgesia may experience a slight increase in the perception of contraction intensity and pelvic floor discomfort.

Table 30-1	Signs of Placental Separation

Signs of Placental Separation	Physiologic Explanation
A small gush of blood	With separation, some blood escapes from between the placenta and the decidua.
Lengthening of the umbilical cord	As the placenta descends into the vagina, the cord lengthens at the vaginal introitus.
Rise of the uterus into the abdomen	As the placenta descends into the vagina, the uterus is displaced cephalad.
The uterus becomes firm and rounded	Once the placenta is expelled from the uterus, the uterine smooth muscles contract more firmly, altering the shape of the uterus.

Placental Expulsion

Expulsion of the placenta occurs by one of two mechanisms: Shultz or Duncan. The majority of the time the Schultz mechanism occurs, although both mechanisms are considered normal.

In the *Schultz mechanism*, the placenta separates centrally. The fetal side of the placenta—the side with a smooth, shining membrane continuous with the sheath of the chorion (which also covers the umbilical cord)—drops to the lower portion of the uterus, and then exits through the cervix into the vagina and onto the woman's pelvic floor. At that point, the placenta is expelled, fetal side first. The membranes are expelled last, with the maternal side of the placenta inside the amniotic sac. This mechanism, in effect, inverts the placenta and amniotic sac and causes the membranes to peel off the remainder of the decidua and trail behind the placenta. The majority of bleeding that occurs during this mechanism may remain hidden until the placenta and membranes are expelled, as the blood is captured behind the placenta and inside the amniotic sac (**Figure 30-1**).

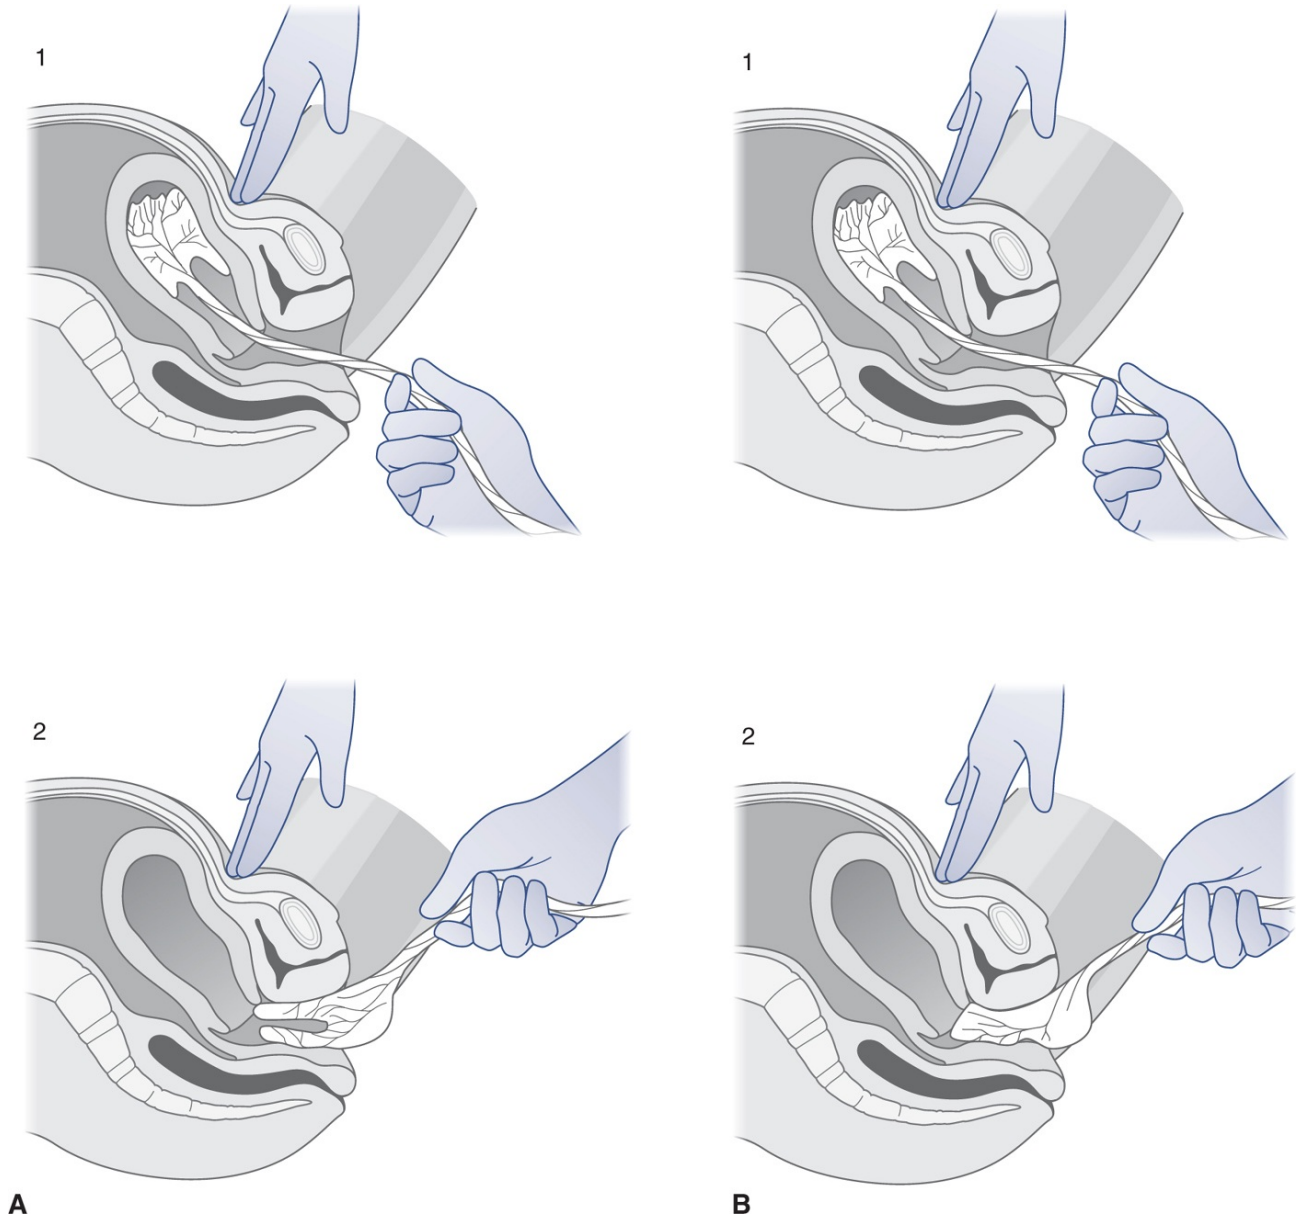

Figure 30-1 Mechanisms of placental expulsion. **A.** Schultz. **B.** Duncan.

In contrast, in the *Duncan mechanism*, the placenta separates marginally. During this process of expulsion, the placenta slides into the cervical opening without inverting, so that the maternal side of the placenta, with dark red cotyledons, is expelled at the same time as the fetal side. Blood escapes between the membranes and uterine wall and is more likely to be visible externally earlier in the separation process. The amniotic sac is not inverted but trails behind the placenta.

The memory aid for correctly identifying the mechanisms of placental expulsion is based on the appearance of the two different sides of the placenta first seen at the vaginal introitus. The fetal side is shiny and glistening from the fetal membranes covering the placenta, whereas the maternal side is dark and beefy—hence the sayings “Shiny Schultz” and “Dirty Duncan.” In past years, some sources have suggested that there is a higher risk of postpartum bleeding when trailing membranes are apparent (as in the Duncan mechanism), but no evidence has been found to substantiate this belief.

Management of the Third Stage of Labor

Although research in the area of third-stage management has been increasing, little is known about how the first and second stages of labor affect the third stage. The primary focus of routine management techniques used during the third stage of labor is to prevent postpartum hemorrhage. Evidence-based management of the third stage is controversial and practices vary. Best practice is rapidly evolving as research identifies new evidence.

The two standard approaches to third-stage management are commonly described as physiologic (expectant) management and active management.[11] The physiologic approach is a noninterventionist approach.[12] This strategy is more commonly followed by midwives in many parts of the world compared to active management.[13-15] Nevertheless, active management is the approach recommended by the International Confederation of Midwives (ICM), the International Federation of Gynecologists and Obstetricians (FIGO), and the WHO based on their interpretation of data reporting decreased PPH.[9,16] **Table 30-2** compares these two approaches. Studies have shown that birth attendants and birth facilities often use a mixed approach that incorporates portions of each approach, rather than strictly following one or the other.[15,17,18]

Table 30-2 **Comparison of Physiologic and Active Management Approaches to Management of the Third Stage of Labor**

Intervention	Physiologic Management	Active Management
Maternal positioning	Upright positioning of the woman to promote gravity assistance	Not addressed
Delayed cord-clamping	Yes	WHO recommends delayed cord-clamping ICM/FIGO has a footnote attached to the recommendation for controlled cord-clamping stating that delaying cord-clamping by 1 to 3 minutes reduces anemia in the newborn
Cord traction	No—generally a “hands-off” approach with spontaneous expulsion by the mother	Yes—continuous gentle cord traction following signs of placenta separation
Maternal efforts to expel the placenta	Delivered with aid of gravity or maternal efforts	Not addressed
External uterine massage following placental expulsion	No—generally a “hands-off” approach to the uterus	Yes (ICM/FIGO only)
Routine administration of a uterotonic agent	No	Yes
Early infant suckling	Yes	Not addressed
Draining the umbilical cord	Not addressed	Not addressed

Active Management of the Third Stage

Active management of the third stage of labor has been shown to decrease the risk of postpartum hemorrhage in a general perinatal population.[11] The most recent meta-analysis of active management protocols compared active management of the third stage of labor to physiologic management for the Cochrane Collaboration.[11] Women in the active management arm had a significant reduction in estimated blood loss exceeding 500 mL (relative risk [RR], 0.33; 95% CI, 0.20–0.56; *n* = 2941), blood transfusion (RR, 0.30; 95% CI, 0.10–0.88; *n* = 3134), and need for therapeutic uterotonic administration (RR, 0.15; 95% CI, 0.11–0.21; *n* = 3134) compared to women whose third stage of labor was managed expectantly.[11] Thus, this strategy is of particular import in low-resource settings where treatment of women with postpartum hemorrhage is not readily available.

The active management approach initially evaluated in randomized controlled trials (RCTs) included four elements: (1) controlled cord traction to facilitate placental expulsion, (2) early cord-clamping and cutting, (3) the routine administration of a prophylactic uterotonic, and (4) fundal massage (in some studies).[10] However, the individual components of active management were not well studied, and each has possible adverse consequences when examined independently. In addition, the management of first and second stages of labor also may influence the third-stage management, but third-stage management has not been studied in association with management that occurred during labor.[12] Therefore, as active management of labor protocols have evolved, some individual components have been deleted from the package of care practices.

The ICM/FIGO joint statement recommends three steps: (1) controlled cord traction (once pulsation stops in a healthy newborn); (2) use of a uterotonic agent; and (3) fundal massage after expulsion of the placenta.[16] Early cord-clamping was not included in this recommendation because delayed cord-clamping has known positive benefits for the newborn.[19-21] The WHO recommends use of a uterotonic agent in all settings, but controlled cord traction only in settings where a skilled birth attendant is present; in support of this recommendation, the WHO cites evidence that both controlled cord traction and early cord-clamping can be harmful to the mother and the infant, respectively.[9] Sustained fundal massage is not recommended by the WHO.[9]

Since the initial active management protocols were published, controlled cord traction, uterotonics, fundal massage, and early versus delayed cord-clamping have all been the subject of considerable research.[19-25] As new information has emerged, the recommended components

of active management have further evolved.[11,26] Current evidence suggests that the administration of a uterotonic agent during the third stage of labor is the most effective treatment for prevention of postpartum hemorrhage and likely the only component within the active management triad that has consistent clinical utility.[26]

A variety of uterotonic drugs are available, and controversy exists about the best route, dose, and timing when used as part of an active management of the third stage protocol. Current guidelines from the ICM/FIGO and the WHO recommend oxytocin (Pitocin) 10 U administered intramuscularly or intravenously after being diluted in solution as the first-choice agent.[9,16] Although the guidelines refer to administration of oxytocin after the birth of the infant, this medication can be given as the anterior shoulder is released under the symphysis pubis, during the birth of the neonate, after the birth of the infant, or after placental expulsion. The timing does not influence the amount of bleeding or the rate of postpartum hemorrhage.[27] Administration of a uterotonic agent with the birth of the neonate is effective and safe unless the woman has a multifetal gestation with another fetus in the uterus. Some midwives have expressed concern that administering the uterotonic before the placenta is expelled will increase the risk of an entrapped placenta; however, this outcome has not occurred in any of the studies of uterotonics, so it remains a theoretical concern that does not have supporting clinical evidence.

Physiologic Management

Physiologic management of the third stage of labor includes no routine uterotonic administration, delayed cord-clamping, and gentle—if any—cord traction. Maternal efforts to expel the placenta are encouraged. A Cochrane Collaboration analysis found heterogeneity in how the components of physiologic management were implemented in the studies analyzed.[11] However, the analysis also found that there were no significant differences in the risk for severe postpartum hemorrhage (RR, 0.31; 95% CI, 0.05–2.17; n = 2941) among women who did not have an a priori risk for postpartum hemorrhage when active management was compared to expectant management.

A secondary analysis of data from RCTs suggests that prophylactic oxytocin (Pitocin) for women who do not receive intrapartum oxytocin for induction or augmentation for the reduction of postpartum hemorrhage (greater than 1000 mL) may not have the same protective effect as for women who already have received intrapartum oxytocin.[12] Therefore, women who are at low risk for postpartum hemorrhage may be offered physiologic management in settings that have ready access to treatments for postpartum hemorrhage, whereas active management may be more beneficial in low-resource settings.

Mixed Management

Mixed management incorporates some components of both active and physiologic management of the third stage and is common practice. The primary change in practice that has resulted in a mixed management strategy is the introduction of delayed cord-clamping, which has proven benefits for the newborn.[19] In this scenario, a midwife may routinely administer a uterotonic

agent after the birth but delay clamping the cord either for an arbitrary period of time or until it stops pulsating, then apply gentle controlled cord traction.[19] In clinical practice, the combination of a midwife's usual practice, the birth site, institutional or practice guidelines, the birthing woman's history, and birth situation, along with the woman's particular preferences likely influence how the third stage of labor is managed and rarely conforms strictly to either expectant or active.

A survey of midwives and physicians reported more than 100 interventions that they or others may use during the third stage of labor.[14,17] However, the myriad techniques used during the third stage were found to cluster into distinct practice patterns ranging from primarily hands-off care to higher hands-on interventions.[17] The effect of these patterns—that is, these clusters of care practices—on the rate of postpartum hemorrhage remains unknown.

Uterotonics to Prevent Postpartum Hemorrhage

Although oxytocin (Pitocin) is the first choice for postpartum hemorrhage prophylaxis, it may not be as effective for women who received large doses of oxytocin during labor for induction or augmentation.[12] In this case, a different uterotonic agent may be indicated. Ergot alkaloids (methylergonovine maleate), prostaglandins, and Syntometrine (an oxytocin/ergometrine combination drug not available in the United States) are second-line prophylactic uterotonic agents.[28] Misoprostol is not as effective for prophylaxis but may be used if other uterotonics are not available.[28]

The routine use of oxytocin, or any other uterotonics, with normal saline via umbilical vein injection has not been found to be effective and should not be used for prevention of postpartum hemorrhage.[29] The effectiveness of complementary treatments such as herbs or homeopathic remedies for postpartum hemorrhage reduction is still unclear.[30]

Cord Traction

Continuous cord traction initially was recommended as part of the active management package, along with early cord-clamping, because of concerns related to early administration of a uterotonic agent—namely, the belief that the placenta should be expelled quickly to avoid entrapment when the cervix reconstitutes. However, entrapment of the placenta has not been found to occur in studies that evaluated delayed cord-clamping,[31] and the rationale for controlled cord traction is less convincing.

Gentle cord traction is needed to guide the placenta out of the vagina once the placenta has separated. Following signs of placental separation, the midwife applies gentle counter-traction to the lower uterine segment abdominally with one hand, while the other hand applies continuous gentle downward traction on the cord. An instrument such as a hemostat is used to clamp the umbilical cord close to where the cord exits the introitus; alternatively, a piece of gauze can be wrapped around the cord to promote easy traction. The traction should follow the curve of Carus. For example, if the woman is in a semi-recumbent position, the cord is guided inferiorly as the placenta descends to the pelvic floor, and as the placenta becomes visible at the introitus, the cord is guided superiorly.

If the woman is in a squatting or other upright position, cord traction is likely not necessary and may even be dangerous. Excessive cord traction increases the risk for uterine inversion—a risk that theoretically might be further increased if the woman is in an upright position. A woman in an upright position will likely feel the pressure of the placenta as it descends to the pelvic floor and spontaneously expel it.

Umbilical Cord Drainage

Umbilical cord drainage in the third stage of labor involves the removal of the clamp from the previously clamped and cut umbilical cord (after necessary cord blood samples have been obtained) and the draining of the blood from the cord and placenta. In a meta-analysis of three RCTs (n = 1257), Soltani et al. found that cord drainage may reduce the length of the third stage of labor by approximately 3 minutes and total blood loss by less than 80 mL when compared to no cord drainage.[32] It is questionable whether this is a clinically important finding. No decrease in third-stage complications was found when the umbilical cord was drained as compared to when the umbilical cord was not drained.[32] If umbilical cord drainage is incorporated into third-stage management, the blood should not be counted in the estimated or weighed measurement of maternal blood loss, as this is fetal blood. In some settings, such as an out-of-hospital birth site, disposal of the blood may be more problematic than when it is retained in the placenta.

External Uterine Massage Following Placental Expulsion

Uterine massage following the expulsion of the placenta is a component of active management of the third stage of labor that is recommended by both ICM and FIGO.[16] However, the precise benefit (if there is one) of routine external uterine massage is still undetermined.

One RCT has been published that compared uterine massage to no uterine massage in three groups of women who received uterine massage, uterotonics, or both, respectively.[33] The incidence of blood loss of more than 300 mL and need for more uterotonics was statistically higher in the women who received uterine massage only.[33] Nevertheless, when oxytocin (Pitocin) was used, there appeared to be no additional benefit from uterine massage.

If a uterotonic agent is administered, external massage may not further increase the protection against an early postpartum hemorrhage; moreover, it can cause significant maternal discomfort.[34] Uterine massage before expulsion of the placenta is not recommended because if the uterus is massaged before the placenta separates from the uterine wall, the massage may cause incomplete separation of the placenta, resulting in iatrogenic hemorrhage.

Maternal Blood Loss Measurement

Measurement of maternal blood loss at birth provides objective data that will help inform care of the woman following birth. Visual estimation of blood loss has been routine practice for many years, although repeated studies have demonstrated the inaccuracy of this simple method.[35] If a large blood loss occurs in the immediate postpartum period, the amount is

commonly underestimated visually.[35-37] If visual estimation is the usual method of evaluating blood loss, it is beneficial to have experience through regular laboratory simulation to improve estimation accuracy.

Although training improves the accuracy of blood loss estimation, alternative quantitative methods of assessing blood loss are recommended. Two methods that are relatively easy to implement are measuring and weighing. A calibrated under-buttocks drape can be used to measure blood loss. If a calibrated drape is not available or the woman gives birth in a position that does not allow for an under-buttocks drape (e.g., supported squat), weighing blood-saturated items can be implemented. Because *1 gram is equivalent to 1 milliliter in volume*, weighing blood-saturated items and subtracting the weight of the item when dry provides a relatively accurate quantitative measurement of blood loss. Either the pads or calibrated drapes should be used immediately after birth to limit additional content such as amniotic fluid or urine from being included in the blood loss measurement.

Some birth sites routinely obtain a quantitative measure of blood loss; however, this step can also be instituted if blood loss is estimated to be higher than normal to improve accuracy and guide management. **A** worksheet with the weight of commonly used items can be used to expedite the process of calculating a quantitative measure of blood loss.[38,39] Some hospitals have incorporated these calculations into their electronic medical records.[39]

Midwifery Management of the Third Stage of Labor

The sequential steps for midwifery management of the third stage of labor are presented in **Appendix 30A**.

Supporting Women's Choices

Maternal requests for nonintervention during the natural progress of the third stage are important to address prior to labor. The process of shared decision making will include discussion of ways to support normalcy during the third stage and the evidence for interventions known to minimize the risk for postpartum hemorrhage. Prenatal preventive measures such as a healthy diet to prevent anemia will lessen adverse effects of blood loss at birth. Avoiding procedures during labor and birth that increase postpartum blood loss, such as induction, augmentation, and episiotomy, also decreases the risk of hemorrhage. Conversely, it is important to remember that delaying the use of uterotonics until bleeding is excessive may increase a woman's risk of hemorrhage.

The placenta, cord, and membranes have special cultural or spiritual significance in many cultures. In turn, additional maternal requests for third-stage management reflecting these beliefs may be quite varied. Rituals related to the placenta exist in many cultures today, and the woman or family may want to save the placenta for a variety of purposes. The ritual of burying the placenta may be undertaken for the purpose of protecting the child, protecting the woman, or establishing a spiritual or sacred link between the land and the child.[40,41] Parents may also be interested in leaving the placenta attached to the newborn until the cord falls off spontaneously, often referred to as a lotus birth.[41] Some women practice placentophagy or consume the placenta, raw or cooked, or encapsulated in pill form with the hope of preventing postpartum depression or as a galactogogue, although findings related to these practices generally have been inconclusive.[41-43]

Rituals also may involve the umbilical cord and even the membranes. The cord may be kept as a charm or used for medicinal purposes. Traditionally, when a newborn is born in a caul (i.e., with membranes covering the head), it means that the child will never drown; thus these membranes have been sold to sailors for protection.

When a woman has a special request, the focus should be on safety while also attempting to honor her request. Honoring the variety of beliefs surrounding this amazing organ is important whenever possible following a process of shared decision making.

Examination of the Placenta and Placental Pathology

After the uterus is evaluated and massaged, and the uterine bleeding has slowed, a methodical inspection of the placenta should be performed. Routine inspection of the placenta assists in recognition of abnormal findings and reduces the likelihood of overlooking a significant finding. The steps for inspection of the cord, placenta, and membranes are reviewed in **Appendix 30B**.

Table 30-3 lists common variations noted with the cord, placenta, and membranes. Some

variations, such as a true knot in the cord, may be simple incidental findings yet also associated with an increased risk for newborn morbidity. When observed, their presence should be noted in the health records of both the woman and the newborn.

Table 30-3 Umbilical Cord, Placenta, and Membrane Variations

Variation	Significance
Umbilical Cord	
Two-vessel cord	A two-vessel cord occurs among 0.5% to 1% of neonates. Two-vessel cords are associated with gastrointestinal, genitourinary, and cardiovascular abnormalities.
Long cord	A long cord, more than 75 cm, is associated with knots and fetal entanglement, as well as increased amniotic fluid and fetal activity.
Short cord	Short cords, less than 32 cm, are associated with disorders that limit fetal movement, such as neuromuscular disorders, fetal limb dysfunction, and Down syndrome. Short cords are associated with fetal heart rate abnormalities in labor as a result of traction on the cord with fetal descent.
Thin cord	Associated with oligohydramnios and poor fetal growth.
Thick cord	Associated with polyhydramnios and macrosomia.
Marginal (Battledore) insertion	The cord is inserted at or within 1.5 cm of the margin of the placenta. May be an insignificant finding but is associated with preterm labor, abnormal fetal heart rate patterns in labor (compression), and bleeding in labor (vessel rupture).
Velamentous insertion	The umbilical cord vessels run through the amnion and chorion before entering the placenta, leaving the vessels unprotected (see **Figure 30B-3**). This type of insertion may lead to rupture and fetal hemorrhage, particularly if associated with vasa previa (transcervical position). This finding is more common in twin placenta.
Knots, loops, torsion, or strictures	These variations are associated with increased fetal mortality and morbidity.
Placenta	
Pale placenta	A pale placenta is associated with immature neonates and anemia. Edematous, pale, and bulky placentas are seen with immune and nonimmune hydrops fetalis, twin-to-twin transfusion syndrome, fetal congestive heart failure, and infection.
Green-stained placenta	With extended exposure to meconium, a placenta may be stained green.
Calcifications	The maternal surface is usually smooth but may have gritty white areas of calcification. Generally, the quantity of calcifications has no clinical importance.
Missing cotyledon	Incomplete expulsion of the placenta. It is associated with uterine atony and postpartum infection.
Small, light placenta	A small placenta is less than the 10% percentile for gestational age and may be associated with intrauterine infections, genetic mutations, or hypertension.
Large, heavy placenta	A large placenta, more than the 90% percentile for gestational age, is often due to various maternal or fetal conditions such as maternal diabetes, fetal erythroblastosis and fetal hydrops, fetal congestive heart failure, and maternal–fetal syphilis.
Infarctions	A localized area of ischemic tissue necrosis that occurs when the villus blood supply is obstructed. Placental infarctions are most common at the periphery of the placenta. Small infarctions are normal variants. Larger infarctions are associated with hypertension, stillbirth, placental abruption, and fetal growth restriction. Any condition that interferes with uteroplacental circulation can lead to placental infarcts.

Nodules or plaques on the fetal surface	Associated with oligohydramnios and renal agenesis, squamous metaplasia (benign), and infection.
Foul odor	Associated with infection.
Placenta	
Circumvallate placenta	With this configuration, the membranes appear to arise not from the edge of the placenta, but rather a short distance inward toward the umbilical cord. As a consequence, the area of the chorionic plate is reduced. Fetal membranes fold back upon themselves, creating a dense, gray/white ring that surrounds the outer margin of the placenta. The fetal vessels stop at this ring. The risk of placental abruption is increased with this variation. Possible causes include a variety of developmental abnormalities. Usually this finding is insignificant, but it has been associated with threatened abortion, preterm labor, painless vaginal bleeding after 20 weeks' gestation, placental insufficiency, fetal growth restriction, and intrapartum and postpartum hemorrhage.
Marginate or circummarginate placenta	A form of circumvallate placenta in which the fetal membranes do not fold back, creating the white ring. In this variation, placental tissue appears to extend beyond the marginate ring where the membranes arise. Usually this finding is insignificant.
Succenturiate placenta	One or more smaller accessory lobes of placenta are developed in the membranes and are attached to the main placenta by fetal vessels. This finding is more common in multifetal gestations. The accessory lobes may be retained, leading to postpartum hemorrhage or infection. These placentas can be associated with velamentous insertion of the cord.
Bilobate placenta	Also referred to as bipartite or duplex. A placenta with three or more lobes is referred to as multilobate.
Membranes	
Cloudy membranes	Associated with infection.
Incomplete membranes	Remnants of membranes are usually spontaneously expelled after the birth; however, they can cause subinvolution of the uterus, uterine atony, or infection if retained.

Placental Pathology

Placental evaluation by a pathologist is not indicated for all placentas. A pathology examination of the placenta can be diagnostic in some situations, however, and the College of American Pathologists has published recommendations for when placental pathology examination should be performed.[44] For example, a pathology examination of the placenta can help establish a diagnosis when stillbirth occurs.[45] Placental pathology is commonly organized into four categories:

- Identification of a previously unsuspected disease process in the woman or neonate that requires immediate attention (e.g., unusual infection such as *Listeria*)
- Conditions with a high probability of subsequent reoccurrence (e.g., placenta accreta)
- Information that can guide management of future pregnancies or influence long-term care of the woman or neonate (e.g., spontaneous preterm birth with histologic chorioamnionitis)
- Diagnosis that provides an explanation for an adverse outcome such as fetal death or growth restriction[46]

A detailed placental pathology examination may provide valuable information or an explanation for neonatal neurodevelopmental impairment or other adverse pregnancy outcomes.[47,48] **Table 30-4** lists some of the clinical scenarios that are commonly cited as indications for requesting a detailed pathology examination of the placenta.[44,48]

Table 30-4 Clinical Conditions That May Indicate Pathology Examination of the Placenta After Birth

Maternal Indications[a]	Fetal or Neonatal Indications	Placental Indications
Abruption, unexplained third-trimester bleeding, or excessive bleeding	Congenital anomalies	Gross placental abnormalities (shape, infarct, mass, amnion nodosum, abnormal coloration, malodor, thrombosis)
Infection during this pregnancy (e.g., human immunodeficiency virus, syphilis, cytomegalovirus, parvovirus, primary herpes, toxoplasmosis, rubella, Zika)	Fetal growth restriction or birth weight less than 10th percentile	Morbidly adherent placenta
Invasive procedure with suspected placental trauma	Gestational age < 34 weeks or > 42 weeks	Placental abruption
Maternal fever or chorioamnionitis	Hydrops fetalis	Umbilical cord abnormalities (long or short, marginal or velamentous insertion, two-vessel cord)
Maternal trauma	Infection or suspected neonatal sepsis	
Oligohydramnios	Neonatal neurologic problems (e.g., seizures)	
Polyhydramnios	Newborn with abnormal umbilical cord blood gas values, low Apgar scores or requiring NICU admission	
Systemic disorder with clinical concerns for mother or neonate (e.g., autoimmune disease, diabetes, hypertension, collagen disease, seizures, severe anemia, thrombophilias or thromboembolic disorder)	Multifetal gestation	
Substance abuse	Stillbirth/early neonatal death	
	Thick meconium	
	Vanishing twin first trimester	
	Very-low-birth-weight infant	

[a] Some experts recommend placental pathology be performed if the woman experienced ruptured membranes for > 24 hours.

Based on Langston C, Kaplan C, Macpherson T, et al. Practice guideline for examination of the placenta: developed by the Placental Pathology Practice Guideline Development Task Force of the College of American Pathologists. *Arch Pathol Lab Med.* 1997;121:449-476[44]; Curtin WM, Krauss S, Metlay LA, Katzman PJ. Pathologic examination of the placenta and observed practice. *Obstet Gynecol.* 2007;109:35-41.[48]

Complications of the Third Stage of Labor

Although most births end with an uneventful third stage of labor, some of the most severe childbirth complications occur during the third stage, including retained placenta, placenta accreta, and uterine inversion. Postpartum hemorrhage can occur in the third stage of labor or in the first hours postpartum.

Retained Placenta

When active management of the third stage is practiced, the length of the third stage should be less than 20 minutes, and 98% of women will have expelled the placenta by 30 minutes after birth of the newborn.[49] Following physiologic management of third-stage labor, 98% of women will have expelled the placenta by 60 minutes after birth of the newborn.[50]

Risk factors for a retained placenta include previous retained placenta, previous uterine curettage, preterm birth, preeclampsia, augmented labors, birth in a dorsal position, nulliparity, and use of ergotamine (Methergine).[49,51] It is theorized that ergotamine may trap the placenta when this medication is used routinely prior to expulsion of the placenta for prevention of postpartum hemorrhage, as it causes a clonic or tetanic contraction. The mechanism of action of ergotamine contrasts with that of oxytocin (Pitocin), which is not associated with an increased risk for a retained placenta.

The primary risk associated with retained placenta is hemorrhage. The risk of hemorrhage begins to increase at approximately 20 minutes after birth with the placenta not expelled and continues to increase until it plateaus at approximately 75 minutes after birth.[51] A consultation should be obtained once a prolonged third stage has been diagnosed. The midwife may initiate several interventions when the third stage is increasing in length, including encouraging an upright position for the woman, nipple stimulation via encouraging the newborn to breastfeed or manual nipple stimulation, and ensuring an empty bladder, by means of catheterization if indicated.

If the placenta still has not separated following conservative measures and the time interval has passed 30 minutes, the next step is manual removal of the placenta. Nonemergency manual removal of the placenta should occur in a hospital setting, both for reasons of safety and to enable the woman to receive anesthesia or deep analgesia for this usually painful procedure. **Appendix 30C** reviews the procedure for manual removal of the placenta. In the nonemergency situation, the midwife can manually remove the placenta in consultation with a physician or wait for a physician to conduct the procedure. If the woman is hemorrhaging, the midwife may need to manually remove the placenta emergently.

Avulsed Cord

Excessive cord traction before complete placental separation can cause the umbilical cord to detach or avulse from the placenta, necessitating manual removal of the placenta—an intervention that exposes the woman to unnecessary pain and an increased risk of infection. A sensation of tearing will be felt as the cord is detaching. If this is noticed, cord traction should

be discontinued immediately and signs of placental separation should be apparent before resuming. Repositioning the woman in an upright position may facilitate placental expulsion.

Uterine Inversion

Uterine inversion occurs when the fundus collapses into the endometrial cavity, which turns the uterus partially or completely inside out. Uterine inversion is a rare event, occurring in approximately 2.9 in 10,000 births; however, it has been found to occur primarily in women who have low-risk pregnancies.[52] Strong umbilical cord traction and fundal placental implantation are associated with this condition, although it may also occur spontaneously. The uterine inversion can be incomplete (fundus within endometrial cavity), complete (fundus protrudes through the cervical os), prolapsed (fundus protrudes to or beyond vaginal introitus), or total (both the uterus and the vagina are inverted). Incomplete or complete inversions feel like a soft tumor that can be felt in the cervical or vaginal orifice, while abdominally a funnel-like depression may be felt instead of a rounded fundus.

Uterine inversion is associated with maternal shock and disseminated intravascular coagulation (DIC). Thus, this complication can be a life-threatening emergency. Uterine inversion should be suspected and a vaginal examination performed if the woman develops symptoms of shock after giving birth without obvious reason. Excessive bleeding and severe uterine pain may or may not be present. **Appendix 30D** presents the management of uterine inversion and describes the position of the midwife's hands during this maneuver.

Placenta Accreta

Placenta accreta is the term for a placenta that is abnormally adherent to the uterine wall. Placenta accreta is further subcategorized as *placenta increta*, when the placenta invades the myometrium, and *placenta percreta*, when it has extended through the myometrium and uterine serosa and into adjacent tissue, often the bladder. Placenta accreta most often occurs when the placenta implants over an area where there is a deficiency of decidual formation, such as over a uterine scar or in the lower uterine segment.[53] Women who have a cesarean birth are at increased risk for placenta accreta in subsequent pregnancies. Women who have had one or more previous cesarean births and who have a placenta previa in the current pregnancy are particularly at risk for placenta accreta. The risk of occurrence increases with increasing number of cesarean births.

The overall rate of placenta accreta has been reported to range from 1 in 2500 pregnancies to (more recently) 1 in 500 pregnancies.[53] It has been proposed that the increasing rate of placenta accreta is occurring secondary to the rising rate of cesarean births.

If the placenta is completely adherent, there usually is minimal bleeding. If it is partially separated or partially adherent, there will likely be more bleeding, which may or may not be visible. If placenta accreta is suspected due to a retained and adherent placenta, physician consultation and in-hospital care are necessary. Hysterectomy while leaving the placenta intact is generally the recommended treatment for placenta accreta.

Postpartum Hemorrhage

Postpartum hemorrhage can occur at any time in the first 6 weeks postpartum and is divided into two types. Postpartum hemorrhage is termed *early* or *primary* when it occurs within the first 24 hours postpartum; in contrast, it is described as *late* or *secondary* when it occurs after 24 hours and up to 6 weeks postpartum.[54,55]

Internationally, postpartum hemorrhage is the leading cause of maternal mortality. The incidence of early postpartum hemorrhage—and especially severe hemorrhage requiring blood transfusion—has markedly increased in the last several years in many developed nations, including the United States.[56] Although many factors are involved in the increasing incidence of postpartum hemorrhage, a significant proportion of this increase is associated with more frequent use of oxytocin for augmentation and cesarean section birth.[56] In the United States, postpartum hemorrhage occurs in 2% to 3% of all births but is the cause of 20% of all maternal deaths.[56] Most importantly, more than half of all maternal deaths attributed to hemorrhage are preventable. In developed nations where adequate resources are present, these deaths are mostly attributed to failure to coordinate the management of this emergency.[57]

Identification of risk factors, preventive measures, and early detection and management can help mitigate the adverse consequences of this complication. Over the last several years, use of simulation, clinical guidelines, bundles, and checklists has been promoted as a means to improve how a team responds and manages emergencies. Use of guidelines for managing postpartum hemorrhage has lowered the incidence of severe maternal morbidity,[58] and a list of these resources is included at the end of this chapter.[59,60]

Approximately 800–1000 mL of blood flows to the gravid uterus each minute. Thus, significant blood loss can occur quite quickly if the uterus does not contract effectively immediately after birth.

Postpartum hemorrhage has been defined in several ways in the past. In 2014, to encourage standardization, a U.S. multidisciplinary collaborative, including member representation from the American College of Nurse-Midwives, defined early postpartum hemorrhage as a cumulative blood loss of 1000 mL or more or blood loss accompanied by sign/symptoms of hypovolemia within 24 hours following the birth (including intrapartum loss).[55] Previously, the generally accepted definition was a blood loss of more than 500 mL after a vaginal birth or more than 1000 mL blood loss following a cesarean birth.[54] Most healthy women, however, can tolerate a blood loss of 1000 mL without adverse consequences. Moreover, estimated blood loss is very often underestimated in clinical settings.[37] In fact, when blood loss is measured, it appears that 500 mL is the *average* blood loss following a normal spontaneous vaginal birth. Thus, the “greater than 500 mL” definition was somewhat arbitrary and not evidence based.

Other authors have suggested that a postpartum hemorrhage occurs when the postpartum hematocrit represents more than a 10-point drop from the prenatal value. This retrospective definition is not clinically helpful during the third stage of labor.

Finally, signs and symptoms of hypovolemia can be used to define a postpartum hemorrhage. Because symptoms such as hypotension and tachycardia appear only after 15% of blood volume is lost, these developments are not a sensitive indicator that the midwife can use to

identify a postpartum hemorrhage in the early stages, at the point when the excessive bleeding needs to be recognized and controlled effectively. In clinical practice, postpartum hemorrhage is a subjective assessment of an estimated blood loss that threatens hemodynamic stability. It is important to initiate steps to control postpartum bleeding before reaching any of these thresholds. Early action in the presence of excessive bleeding may prevent an actual hemorrhage.

Causes of Postpartum Hemorrhage

Table 30-5 lists the most common causes of early postpartum hemorrhage, along with a mnemonic (tone, tissue, trauma, thrombin) that can be used as a memory prompt.[39,60-62] Uterine atony and retained placental fragments are the causes of approximately 80% of early postpartum hemorrhages, although most women who experience a postpartum hemorrhage do not have an identifiable risk factor.[56,62] Late postpartum hemorrhage is most often caused by retained placental fragments, infection, coagulopathies, or subinvolution at the placental site.

Table 30-5 The "Four Ts" Mnemonic for Causes of Immediate Postpartum Hemorrhage

Cause	Etiology	Clinical Presentation
Tone		
Overdistended uterus—large fetus, multifetal gestation, polyhydramnios Prolonged labor (all stages) Rapid labor Oxytocin-induced or -augmented labor High parity Postpartum hemorrhage with previous birth Chorioamnionitis Poorly perfused myometrium—hypotension Medications such as magnesium sulfate, nifedipine, and some general anesthetics Uterine abnormalities such as fibroids	70%	Bright red bleeding, clots, boggy or soft uterus
Tissue, retained		
Avulsed cotyledon, succenturiate lobe Abnormal placentation—accreta, increta, percreta Retained blood clots	20%	Bright red bleeding, clots, boggy or soft uterus
Trauma		
Episiotomy, especially mediolateral Hematoma Lacerations of perineum, vagina, or cervix Ruptured uterus Uterine inversion	10%	Bright red bleeding, firm uterine fundus Hematomas: intense pain at site of bleeding Bright red bleeding firm uterine fundus

		Shock greater than expected from estimated blood loss
Thrombin		
Coagulopathies	1%	Excessive bleeding
Acquired coagulopathies such as placental abruption, amniotic fluid embolism, disseminated intravascular coagulation, HELLP syndrome (i.e., hemolysis, elevated liver enzymes, and low platelet count), stillbirth, or sepsis		
Congenital coagulation defects such as von Willebrand's disease		
Therapeutic anticoagulation

Recent advances in the management of major postpartum hemorrhage: a review. *J Clin Diagnost Res*. 2017;11(2):QE01-QE05. doi:10.7860/JCDR/2017/22659.9463[61]; Evensen A, Anderson JM, Fontaine P. Postpartum hemorrhage: prevention and treatment. *Am Fam Physician.* 2017;95(7):442-449.[62]

Many strategies have been used to identify women who are at risk for excessive blood loss. Stratifying women into low-, medium-, and high-risk groups is valuable as a guide for anticipatory preparation. Even so, most postpartum hemorrhages occur in women who have no risk factors.[55,58,60]

Stages of Postpartum Hemorrhage

As shown in **Table 30-6**, symptoms of hypovolemia usually parallel the amount of blood lost. Thus, postpartum hemorrhage can be categorized as compensated, mild, moderate, or severe depending on symptoms and the amount of blood loss.[59] Women who are already volume depleted, such as those with preeclampsia, may decompensate more rapidly.

Table 30-6 Stages of Hemorrhagic Shock

	Compensated PPH	Mild PPH	Moderate PPH	Severe PPH
Blood volume loss (mL)	< 1000	1000–1500	1500–2000	≥ 2000
Percentage of blood volume lost (%)	10–15	15–30	30-40	≥ 40
Heart rate (bpm)	< 100	> 100	≥ 120	≥ 140
Systolic blood pressure (mm Hg)	Normal	Normal	Hypotension	Profound hypotension
Pulse pressure	Normal or increased	Narrowed	Narrowed	Narrowed
Respiratory rate/min	14–20	20–30	30–40	> 40
Urine output (mL/hr)	≥ 30	20–30	5–15	Slight or anuria
Mental status	Normal	Weakness, sweating, agitation or mild anxiety	Restless, pallor, confusion	Air hunger, collapse, lethargy

Abbreviation: PPH, postpartum hemorrhage.

The first physiologic compensation that occurs when blood loss is excessive is systemic vasoconstriction, which is clinically evident as a narrowed pulse pressure. Systolic blood

pressure begins to fall and pulse rises after 15% to 25% of blood volume is lost. Hypotension and tachycardia are relatively late signs of hemorrhage. Narrowing trends in pulse pressure are a better vital sign to initially monitor when bleeding becomes excessive.

Complications of Postpartum Hemorrhage

Postpartum hemorrhage can result in anemia, hypotension, and, in severe cases, hypovolemic shock that can lead to DIC, adult respiratory distress syndrome (ARDS), and Sheehan's syndrome.

DIC is a consumptive coagulopathy that results in depletion of platelets and coagulation factors. Its etiology is widespread activation of the clotting and fibrolytic systems. This cascade of events is stimulated by circulatory exposure to large amounts of tissue factor, which is present in the placenta. The result is uncontrolled bleeding. Recent studies of postpartum hemorrhage have found that DIC occurs earlier than previously thought.[61] Early treatment of a woman with DIC can significantly improve maternal outcomes. Evaluation of coagulation studies is part of the initial response to postpartum hemorrhage, and transfusion protocols for postpartum hemorrhage recommend treating DIC as soon as it is determined to be a significant risk.

ARDS and Sheehan's syndrome are rare complications of postpartum hemorrhage. ARDS results from damage to the endothelial cells in the pulmonary vasculature that causes fluid to leak into the alveoli, producing respiratory distress. Sheehan's syndrome is the result of pituitary necrosis.[63] The pituitary is perfused via venous pressure, which makes it vulnerable to ischemia and damage in the presence of hypotension. The most common initial symptom of Sheehan's syndrome is failure of lactogenesis II. Amenorrhea, adrenal insufficiency, hyponatremia, and hypoglycemia are additional complications of pituitary hypofunction.

Strategies to Prevent Postpartum Hemorrhage and Minimize Adverse Effects

Strategies to minimize the adverse effects of postpartum hemorrhage include correction of anemia preconceptionally or in the prenatal period, elimination of routine episiotomies, and avoidance of genital tract lacerations.[62] The best prevention strategy during the third stage of labor is active management of the third stage, starting with administration of a uterotonic agent during or immediately following the birth of the infant.[11] **Table 30-7** lists recommended preparations to implement for women at a moderate or high risk of early hemorrhage.

Table 30-7 Management Plan for a Woman at Moderate or High Risk for a Postpartum Hemorrhage

1. Provide anticipatory guidance to the woman and her significant other/family (with the woman's permission).
2. Choose the birth site based on the risk assessment.
3. Prepare a plan of care and communicate it to all healthcare team members, including nursing and anesthesia staff, when a woman is in labor. A physician may be alerted when the woman enters labor based on her level of risk.
4. Based on her risk, the plan of care for the woman in labor may include the following:

a. Order a blood type and screen or type and cross-match for blood if needed.
b. Initiate a large-bore intravenous line during labor (at least 18 gauge) for rapid access.
c. Catheterize the woman's bladder if it is full and she is unable to void, as a full bladder may impede postpartum uterine contraction effectiveness.
d. Consider pain management methods that will support the steps undertaken to manage a postpartum hemorrhage, and make a plan with the woman early in her labor.
e. Administer a uterotonic agent with the release of the neonate's anterior shoulder, assuming there is assurance that a second fetus does not exist.
f. Promptly initiate and maintain uterine massage after placental expulsion and continue close observation for bleeding.

If hemorrhage occurs, proceed to the steps outlined in Appendix 30E.

Management Steps for Treating Postpartum Hemorrhage

Vital signs such as narrowing pulse pressure or quantified blood loss can be used as a trigger or alert to initiate treatment guidelines and team assistance.

Table 30-8 summarizes the dose, contraindications, and side effects of the uterotonic agents commonly used to treat postpartum hemorrhage.[64-66] Oxytocin (Pitocin) is considered the first-line uterotonic. If the hemorrhage does not resolve with its use, second-line drugs—such as methylergonovine maleate (Methergine) or one of the prostaglandin analogues—are administered. Tranexamic acid is a fibrinolytic agent that has recently been studied for prevention and treatment of women with postpartum hemorrhage. Data from the few available RCTs that have been published suggest use of tranexamic acid decreases the incidence of maternal mortality when it is used to treat postpartum hemorrhage.[65] Further studies of this agent are needed to determine its adverse effects and relative effectiveness.

Table 30-8 Uterotonic Treatment of Immediate Postpartum Hemorrhage Due to Uterine Atony

Drug Generic (Brand)	Dose and Route	Contraindications	Side Effects	Clinical Considerations
First-Line Therapies				
Oxytocin (Pitocin)	10–80 U in 250 or 500 mL of normal saline or lactated Ringer's solution OR 10 U IM injection	Hypersensitivity	Cramping Large doses can cause hyponatremia	Onset of action: 2–3 min Effective in 15–30 min Duration of action: 2–3 hr if given IM Rapid infusion of an undiluted bolus can cause hypotension and cardiac collapse
Second-Line Therapy				
Methylergonovine maleate (Methergine)	0.2 mg IM May repeat in 5 min Thereafter every 2–4 hr	Hypertension, preeclampsia Do not give IV secondary to risk of sudden vasospasm and hypertensive or cerebrovascular accident	Cramping Nausea, vomiting Hypertension, seizure, headache	It is recommended that the woman's blood pressure be taken prior to administration Onset of action: 2–5 min Peak plasma concentration: 20–30 min Plasma half-life: 3–4 hr Women with coronary artery disease may have increased risk for myocardial infarction FDA black box warning to avoid breastfeeding for first 12 hours of newborn's life
Carboprost tromethamine or 15 methyl prostaglandin $F_{2\alpha}$ analogue (Hemabate)	250 mcg IM May repeat every 15–90 min, up to 8 doses	Asthma or active cardiac, pulmonary, renal, or hepatic disease	Nausea, vomiting, diarrhea, bronchospasm, hypertension Pyrexia is common	FDA black box warning to use recommended doses only and in a hospital setting as well as to avoid breastfeeding for first 12 hours of newborn's life Peak serum concentration: 30 min Less effective than methylergonovine
Dinoprostone (Prostin E_2)	20 mg vaginal or rectal suppository May repeat every 2 hours	Hypotension Cardiac disease	Nausea, vomiting, and diarrhea Pyrexia is common	FDA black box warning to use recommended doses only and in a hospital setting Onset of action: 10 min
Misoprostol (Cytotec)	600–800 mcg sublingual or 800–1000 mcg per rectum; 1 dose		Nausea, vomiting, diarrhea, abdominal pain Pyrexia can occur with higher doses	Onset of action: 3–5 min Peak concentration: 30 min following sublingual administration; 40–60 min following rectal administration
Tranexamic acid[a] (Cyklokapron)	1 gm IV, can be repeated after 30 minutes		Mild gastrointestinal signs	Recommended by WHO if other measures fail. Inhibits fibrinolysis so has a potential risk of thrombosis.

Abbreviations: FDA, U.S. Food and Drug Administration; IM, intramuscular; IV, intravenous; WHO, World Health Organization.

[a] Tranexamic acid is an antifibrinolytic that is being evaluated for prevention or treatment of postpartum hemorrhage. Contraindications and adverse effects have not been fully elucidated, studies are ongoing.

Burlington, MA: Jones & Bartlett Learning; 2017:1088[64]; WOMAN Trial Collaborators. Effect of early tranexamic acid administration on mortality, hysterectomy, and other morbidities in women with post-partum haemorrhage (WOMAN): an international, randomised, double-blind, placebo-controlled trial. *Lancet*. 2017. pii: S0140-6736(17)30638-4.[65]

Appendix 30E lists the steps recommended for managing a postpartum hemorrhage, and **Appendix 30F** reviews the steps taken to explore the intrauterine cavity if needed.[67-69] Standard procedures that are practiced in simulations or rehearsals can improve the response time when a real postpartum hemorrhage occurs.[57,59] The WHO recommends the development of formal protocols for prevention and treatment of postpartum hemorrhage,[9] although no specific protocol has been established as best practice.

Many sources delineate the sequential steps the midwife should proceed through when

managing a postpartum hemorrhage.[58,59] In addition, the midwife can find some excellent flowcharts that institutions use to guide management of a postpartum hemorrhage. Evidence-based flow charts and pocket algorithms that can be used to help manage obstetric hemorrhage and improve outcomes are available and examples are listed in the Resources section at the end of this chapter.[39]

A combination of bimanual compression and uterotonic drugs controls bleeding in the vast majority of women with postpartum hemorrhage. If management steps are initiated rapidly, excessive blood loss can be avoided. An interprofessional team should be called to address the emergency if the hemorrhage continues despite bimanual compression and use of uterotonic drugs, or if the woman has signs of hypovolemia. The use of agreed-upon vital sign "triggers" that signal the need for more aggressive treatment can help standardize management of postpartum hemorrhage and minimize morbidity. For example, triggers that could signal the need to initiate a hemorrhage protocol could be maternal pulse more than 110 bpm, estimated blood loss more than 500 mL, or systolic blood pressure less than 85 mm Hg. The team that responds to such emergencies commonly includes an anesthesia provider, an obstetric physician, and additional nursing staff. Once the hemorrhage is controlled, close postpartum surveillance is maintained until bleeding is minimal and the woman is stable.

Hematoma

Hematomas are the result of damage to blood vessels. When they occur in association with childbirth, they are most likely to become apparent during the intrapartum or postpartum periods. The most common locations for hematomas are (1) the vulva, (2) the vagina, and (3) the retroperitoneum.[69] The types of hematomas and their initial presentation are described in more detail in the *Genital Tract Injury: Immediate Postpartum Inspection of the Vulva, Perineum, Vagina, and Cervix* appendix in the *Second Stage of Labor and Birth* chapter and management is reviewed in the *Postpartum Complications* chapter.

Hematomas are very painful in women who do not have epidural analgesia, such that pain is the cardinal sign of a developing growth.[69] Women who have a functioning epidural may report sudden rectal pressure. In addition to pain, other clinical indicators of hematoma include signs and symptoms of blood loss such as hypotension or tachycardia.

Because a hematoma may not be visible externally, a gentle internal digital examination is necessary to establish the diagnosis. If the midwife finds a firm, rounded swelling into the vaginal canal or on the vulva that is small and not expanding quickly, it can probably be managed expectantly with frequent observation to make sure it is not expanding, placement of cold packs, and establishing intravenous access in case volume resuscitation is needed (**Table 30-9**). A Foley catheter may be needed to aid urination and a complete blood count to establish a baseline may be indicated. The midwife should communicate to the woman and caregivers (nurses in the hospital or family members if out of the hospital) the importance of reporting increasing pain or swelling.

Table 30-9	**Genital Tract Hematoma: Expectant Management**

Management	Rationale
Frequent assessment	The frequency will depend on when the hematoma is diagnosed, whether it is changing, and how much maternal discomfort is present. Assessments may be spaced out once the hematoma is determined to be stable.
Ice packs to the affected area for 24–48 hours	Ice packs assist with vasoconstriction, thereby decreasing bleeding and edema.
Offer pharmacologic pain management	Even minor hematomas may be uncomfortable. Nonsteroidal anti-inflammatory drugs (NSAIDs) should be adequate for minor hematoma pain, but opioids may be required for larger hematomas.
Encourage side-lying positioning	A side-lying position may relieve pressure and decrease pain. This is often an effective position for assessment and diagnosis of a hematoma. Positioning does not alter the hematoma progression.

If the pain is severe, the hematoma is increasing rapidly, or signs of hypovolemia develop, emergency measures are needed. If the woman is in an out-of-hospital setting, emergency transport is begun. The midwife's consulting physician and anesthesia staff should be notified and immediate assistance requested. The midwife should not incise the hematoma without additional aid because of the potential for hemorrhage. Measures to initiate intravenous fluid volume replacement and possible blood transfusion should be initiated while waiting for the healthcare team.

Rare Emergency Complications

If a newly postpartum woman experiences respiratory impairment, cardiovascular collapse, altered mental status, or loss of consciousness, emergency measures are indicated. The differential diagnoses include pulmonary embolus, anaphylactoid syndrome of pregnancy (i.e., amniotic fluid embolus), septic shock, peripartum cardiomyopathy, and atypical eclampsia, among others. Sudden and rapid deterioration of the woman necessitates a quick response. Initial management steps for any maternal emergency are listed in **Appendix 30G**.[70,71]

Life support measures focusing on adequate oxygenation are important regardless of the cause of the emergency. Once the emergency team is in place, the midwife plays an important role in communicating the past history, including the labor and birth; reviewing how the emergency presented; and identifying which management steps were implemented. Finally, maintaining communication with the family members to keep them informed is a critical component of the management of any maternal emergency that a midwife can perform.

Conclusion

The third stage of labor is critical for a healthy start for the new family. Attention to prevention and early identification and treatment of maternal complications can mitigate potential long-term effects. Witnessing the welcome of a newborn into a family is a sweet reward for the midwife. No matter how hard the midwife may have worked to assist the woman and her significant others through the labor and birth, complimenting the woman and stressing her accomplishment is a gift the midwife can offer in return.

Management of the Third Stage of Labor

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

History

- Previous birth complications during the third stage, including postpartum hemorrhage
- Risk factors for postpartum hemorrhage
- Course of this labor and birth
- Maternal requests for specific management in the third stage of labor

Physical Examination

- Maternal response to birth
- Vital signs stable
- Continuing evaluation of any previous significant findings
- Evaluation of new findings—for example, nausea is unusual in the third stage
- Evaluation of progress of the third stage, including signs of placental separation
- Continual assessment of bleeding

Management Steps

These steps include components of both physiologic management and active management of the third stage of labor. Individual situations may require alterations in the order of individual steps.

1. Maintain or reinstate a calm environment to reduce anxiety and facilitate management of normal progress and treatment of maternal complications if they occur.
2. Communicate the next steps and reassurance to the woman.

3. Check the newborn heart rate by palpating at the base of the umbilical cord and abdomen. If the heart rate is faster than 100 bpm, the newborn is breathing, and there are no obvious abnormalities, place the newborn in skin-to-skin contact on the woman's abdomen or arrange to have the newborn placed skin to skin with a person whom the woman designates for this initial period with the infant.
4. Continue to observe the neonatal transition to extrauterine life while the newborn is in skin-to-skin contact when possible. Note that the midwife conducting the birth has a primary responsibility to the woman during the third stage of labor, not management of the newborn.
5. Administer or request administration of a uterotonic agent, if not already given during birth of the anterior shoulder (optional depending on the woman's risk for postpartum hemorrhage, policies, and amount of bleeding present).
6. Consider upright positioning, which uses gravity to assist with placental expulsion if feasible.
7. If cord blood gases are not indicated, two clamps are needed:
    a. Clamp the cord with two clamps placed close together near the newborn's umbilicus after at least 1–3 minutes or when the cord stops pulsating.
    b. Cut the cord between the two clamps or guide the father, partner, other support person, or birthing woman to do this.
8. If cord blood gases are indicated, four clamps are needed:
    a. Place an initial clamp on the cord near the woman's introitus.
    b. Place two clamps in close approximation to each other on the cord distal (toward the newborn's umbilicus) to the first clamp.
    c. Cut the cord (or have another person cut it) between the last two clamps, and place the newborn on the maternal abdomen or hand off the newborn to another provider as indicated.
    d. Place a fourth clamp close to the first clamp that was placed near the woman's introitus, and cut the cord between these two last clamps. There is now a sealed double-clamped section of cord that can be used to obtain cord blood gases (**Figure 30A-1**).

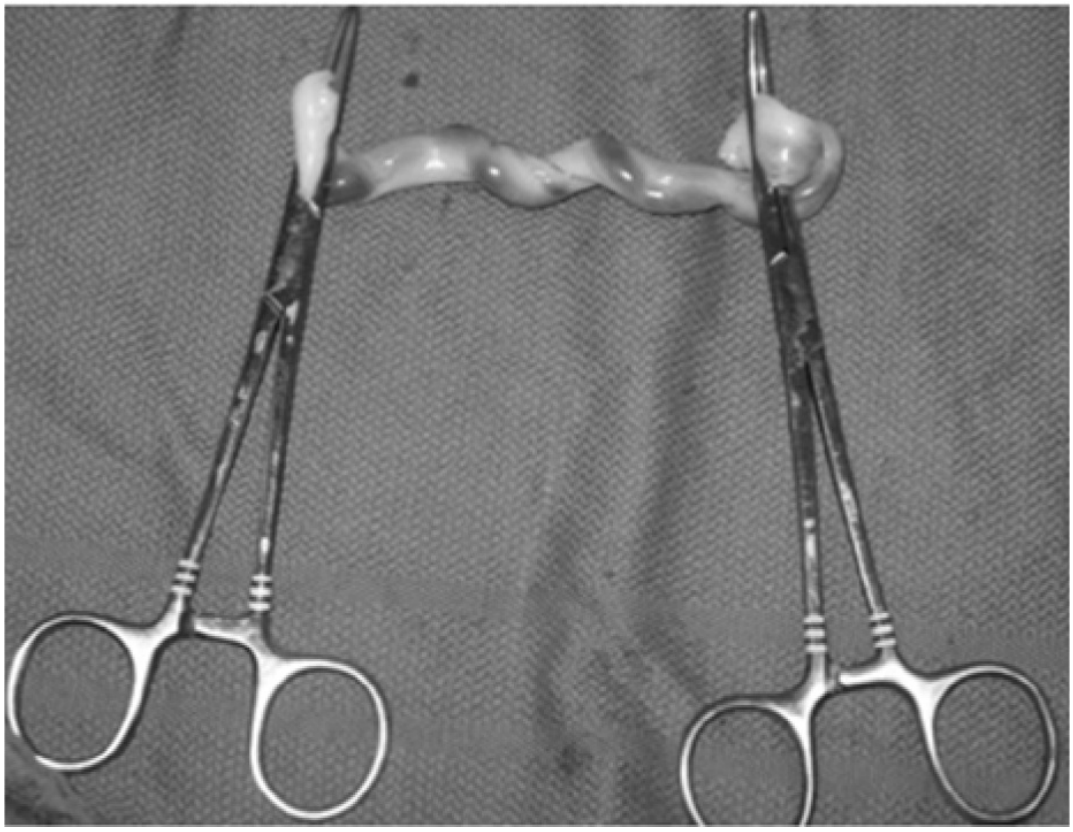

Figure 30A-1 Double-clamped cord.

Photograph courtesy of Tekoa L. King, CNM, MPH.

e. Obtain a sample of blood from the umbilical artery first, and then a sample from one of the umbilical veins, in a heparinized syringe, marking each syringe correctly as from the artery or the vein. Once the syringe is capped, the blood is stable for up to 30 minutes before the blood gas measurement has to be obtained.

9. Inspect the cut end of the umbilical cord and count the number of umbilical vessels.

10. Open the clamp nearest the woman's introitus and allow blood from the placenta to fill a non-heparinized blood collection tube. Approximately 5–10 mL is needed. This blood will be used to determine the type and Rh status of the newborn. Do not milk the cord, as tissue thromboplastin can interfere with the analysis.

11. Observe for signs of placental separation (**Table 30-1**) and do not massage the uterus before placental separation. Massaging the uterus prior to complete separation may increase uterine bleeding or lead to incomplete expulsion of the placenta.

12. Guard the uterus placing a hand suprapubically, anterior to the uterine fundus, to assess for uterine position in the abdomen and prevent uterine inversion as the placenta is expelled.

13. Determine whether the placenta has separated:

a. Use the Brandt–Andrews maneuver (**Figure 30A-2**). Apply slight downward pressure just above the pelvic brim with the hand that is guarding the uterus, while holding the cord taut with the other hand. If the placenta is still in the uterus, the cord will retract as the uterus is displaced upward into the abdomen by pressure from the

abdominal hand. If the placenta has separated and is in the vagina, upward displacement of the uterus will not cause the cord to retract, and additional cord traction can be safely provided while maintaining abdominal counter-traction.

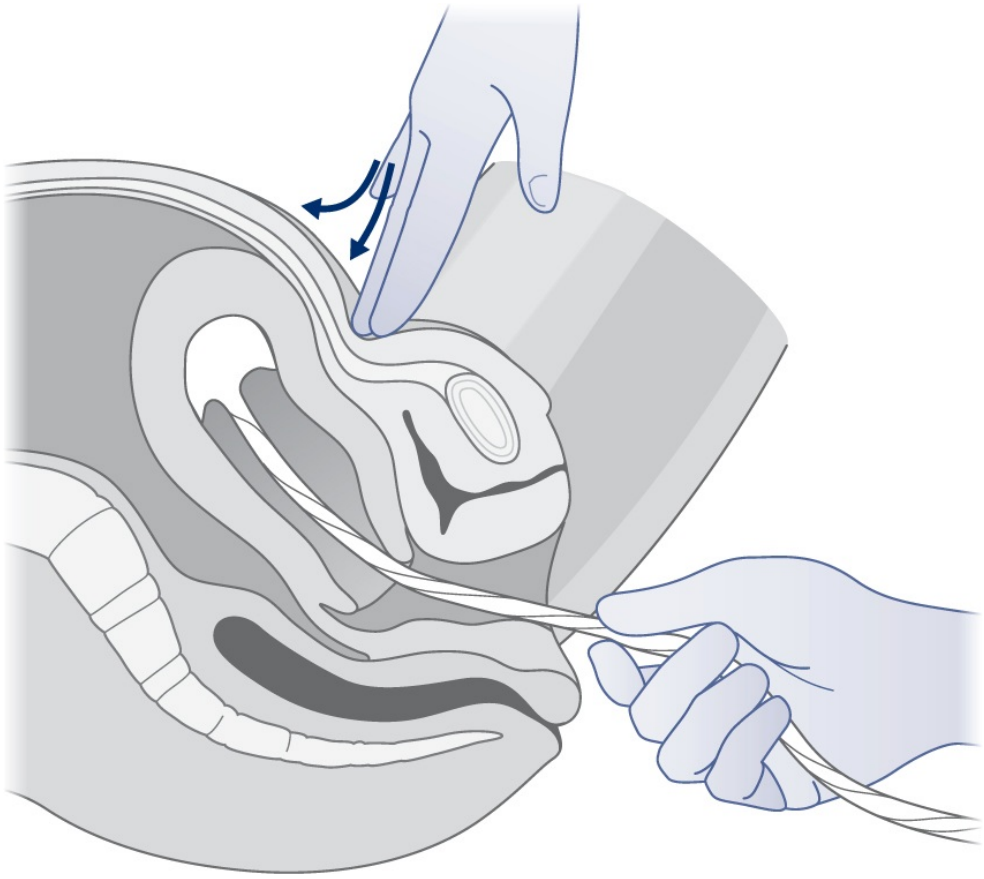

Figure 30A-2 Brandt–Andrews maneuver.

b. Another method of checking for placental location is to slide one finger (using sterile gloves) beside the umbilical cord into the vagina. If the placenta is in the vagina, it will be felt by the tip of the finger. The cord insertion into the placenta feels somewhat like an inverted umbrella. If the cord goes past the cervix, the placenta has not been expelled from the uterus. If the placenta is palpated in the vagina, additional traction can be safely performed.

14. Once the placenta has separated, the woman may spontaneously expel it by pushing. The midwife can also use a combination of the Brandt–Andrews maneuver and controlled cord traction.

15. Cord traction should *not* be performed without guarding the uterus, as this maneuver may result in an avulsed cord or inverted uterus.

16. Grasp the placenta with both hands as it is being expelled. Slowly guide the placenta out, perhaps following the curve of Carus to allow membranes to follow and not tear. If there appear to be more membranes than immediately are expelled, continue to hold the placenta and either twist it slowly or grasp the membranes with ring forceps to gently extract the membranes—a process commonly known as “teasing” out the membranes.

17. Palpate the fundus abdominally to assess if the fundus is firm. Routine vigorous massage to stimulate uterine contraction has not been shown to decrease the incidence of hemorrhage. Such massage may be indicated to express clots through the cervix if excessive bleeding is present, but it is not indicated if the estimated blood loss is normal.
18. Inspect the cord, placenta, and membranes as described in Appendix 30B (**Table 30-3).**
19. Show the placenta to the woman and family if interested.
20. Measure or weigh blood loss.
21. Weigh the placenta.
22. Send the placenta for pathology evaluation if indicated.

APPENDIX

30B

Inspection of the Umbilical Cord, Placenta, and Membranes

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

Inspection of the umbilical cord, placenta, and membranes is performed as soon as the woman and her newborn are stable and comfortable. Any abnormal findings are documented in the maternal and neonatal records. In some situations, a photograph may be of value for documentation.

Inspection of the Umbilical Cord

Count the Number of Vessels

Wipe off the cut end with a gauze or towel if needed. Apply pressure; the apertures of the vessels will be visible. If vessels have collapsed, reclamp and recut the cord, then look for the vessels at the site of the new cut (**Figure 30B-1**).

Figure 30B-1 Counting the number of cord vessels.

Photograph courtesy of Carrie Klima, CNM, PhD.

Three vessels should be visible: two small arteries and one large vein. Any two-vessel cord should be submitted for pathology examination, and neonatal providers should be informed.

Measure the Length of the Cord

If the cord appears abnormally long or short, it should be measured. Remember to include the length of cord cut off the newborn's end when the cord was clamped and cut.

The normal length of a term umbilical cord is approximately 55 to 60 cm (range: 30–90 cm). A long cord, more than 75 cm, is associated with knots and fetal entanglement. Short cords, less than 32 cm, may be associated with limited fetal movement.

Inspect the Cord for Abnormalities

Look for knots, hematomas, tumors, cysts, edema, and the amount of Wharton's jelly (**Figure 30B-2**). The normal width of an umbilical cord is 1 to 2 cm. The width is affected by the amount of Wharton's jelly.

Figure 30B-2 True knot in the umbilical cord.

Photograph courtesy of Carrie Klima, CNM, PhD.

Inspect the Cord Insertion Site

Observe the insertion site for where the cord inserts in relation to the body of the placenta—central, eccentric, or marginal (Battledore placenta). Determine whether the cord is inserted directly into the placenta or is attached by exposed vessels (velamentous cord insertion) (**Figure 30B-3**). Centric and eccentric (off-center) insertions are variations of normal; however, velamentous and marginal insertions are unusual and associated with a risk of vasa previa should one of these vessels tear when the membranes rupture.

Figure 30B-3 Velamentous insertion of the umbilical cord.

Photograph courtesy of Tekoa L. King, CNM, MPH.

Inspection of the Placenta

Inspect the Placenta for Color, Shape, Size, and Consistency

Lay the placenta flat on a surface. Look at the fetal and maternal sides. If necessary, invert the membranes to see both surfaces.

The placental shape is usually round to slightly oval and approximately 2 to 3 cm in thickness. The fetal surface is smooth. The maternal surface is usually smooth with indentations at the edges of cotyledons, but may have gritty white areas of calcification. Generally, the quantity of calcifications has no clinical importance. A pale placenta is associated with immature neonates and anemia. With extended exposure to meconium, a placenta may be stained green.

Inspect the Smooth, Shiny Fetal Side of the Placenta

Inspect for distribution of vessels from the umbilical cord over the surface of the placenta. The fetal blood vessels traverse the surface of the fetal surface from the cord insertion toward the placental margin before turning into the parenchyma, toward the maternal surface. Inspect for cysts and to determine whether this is an extrachorial placenta (either a placenta circumvallata or a placenta marginata). If necessary, invert the membranes to visualize the entire fetal

surface. The fetal surface should also be examined closely for torn or intact blood vessels leading into the membranes so as to identify a missing or intact succenturiate (accessory) lobe.

Inspect the Maternal Side

Examine the placental margin for torn blood vessels leading into the membranes to look for evidence of a succenturiate lobe. A cotyledon missing from the main placental mass is identified by a defect in the placental mass with a rough surface where it tore away or a torn vessel at the edge of the placenta. This must be differentiated from a simple tear in the placenta without loss of tissue, which also leaves a rough surface. Differentiation is made by holding the placenta, maternal surface up, so that the cotyledons fall into place against each other (**Figure 30B-4**). A missing cotyledon is then evident because, as in a jigsaw puzzle, the surrounding pieces will not fit together smoothly. Observe for infarcts, cysts, tumors, and edema.

Figure 30B-4 Midwife examining the maternal side of the placenta. The placenta is intact.

Photograph courtesy of Carrie Klima, CNM, PhD.

Measure and Weigh the Placenta

Measuring and weighing the placenta are usually dictated by policy and are not always routinely performed. A term placenta usually weighs between 400 and 4600 grams. Regardless of the policy in place, if the placenta appears to be of abnormal size, weighing and referring for pathology examination are indicated. This information is then recorded in both the woman's and newborn's health record.

Inspection of the Membranes

Place the placenta maternal side down, and then place a hand inside the membranes on the fetal surface of the placenta and hold the membranes up to simulate the sac they once were (**Figure 30B-5**). If the membranes are ragged and do not form a sac, they may be incomplete. If a portion of the membranes is missing, membranes may still be within the uterus, although this is not a sensitive indicator of retained membranes.

Figure 30B-5 Midwife examining the fetal side of the placenta. The membranes are incomplete.

Photograph courtesy of Carrie Klima, CNM, PhD.

When inspection and documentation are complete, the placenta should be disposed of appropriately. In some cases, families may wish to keep the organ for culturally appropriate disposal, such as planting in their gardens. Others may desire to make impressions of it for a type of placental art. However, midwives should be aware that the placenta has bodily fluids and should be treated with universal precautions.

APPENDIX

30C

Manual Removal of the Placenta

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

A retained placenta occurs in approximately 0.01% to 6.3% of women who have a vaginal birth.[1,2] Although there is no clear consensus on the length of time an unexpelled placenta warrants the diagnosis of retained placenta, the World Health Organization considers the placenta retained if it remains unexpelled longer than 30 minutes, but recommends waiting another 30 minutes before manually removing the placenta unless the woman is actively bleeding.[3] In the United States, the placenta is generally considered retained if not expelled at 30 minutes after the birth, and manual removal is recommended between 30 and 60 minutes if the woman is not actively bleeding.[2]

History

Retained placenta as defined by prolonged time.

Physical Examination

- Evaluation of progress of the third stage of labor, including signs of placental separation.
- Continual assessment of bleeding: Active bleeding may be apparent in the presence of an unexpelled placenta even if time since birth is not prolonged. Active bleeding requires prompt intervention.

Management Steps

1. Explain to the woman and others/family in attendance (with the woman's permission) the problem and the steps needed to resolve the problem.

2. Discuss options of pain management such as opioids, redosing of epidural, and/or nitrous oxide.
3. Alert the birth team (e.g., birth assistant, nurses) regarding the problem and plan for manual removal. Based on the birth site, another provider (e.g., physician, other midwife) with more experience may be immediately available and consulted as appropriate.
4. If an intravenous line is not already in place, insert one using a large-bore (at least 18-gauge) needle, in case a hemorrhage occurs and intravenous fluids are needed.
5. Verify that the newborn is being cared for appropriately. If the woman is holding the neonate, ask another responsible individual to hold the infant or place the newborn in a safe site.
6. Catheterize the woman's bladder as needed, as a full bladder may impede the effective uterine contractions needed after placental removal.
7. Change gloves or put on second pair so that the procedure is as sterile as possible. Gloves of a regular length can be used, but a longer length that overlaps a sterile gown may provide more protection from body fluids.
8. Reduce the diameter of the hand by squeezing the extended fingers close together, and gently insert one hand slowly and steadily through the vagina and past the cervix. The entire hand is inserted to facilitate the ability to perform the procedure. Once inserted, the hand should not be removed until the procedure is complete. Repeated insertion and removal of the hand increases pain and risk of infection for the woman.
9. Using the internal hand, sweep the margin of the placenta to find any area of separation. Once a point of separation is found, rotate the hand so the back of the hand is next to the uterine wall. This placement results in the hand being in a cup-like position and minimizes the risk of inadvertent uterine rupture.
10. Insinuate the fingers between the placenta and the uterus to establish a line of cleavage. Separate the placenta by sweeping back and forth from side to side, cutting through the decidua with the outer edge of the hand, fingertips, and first finger (**Figure 30C-1**).

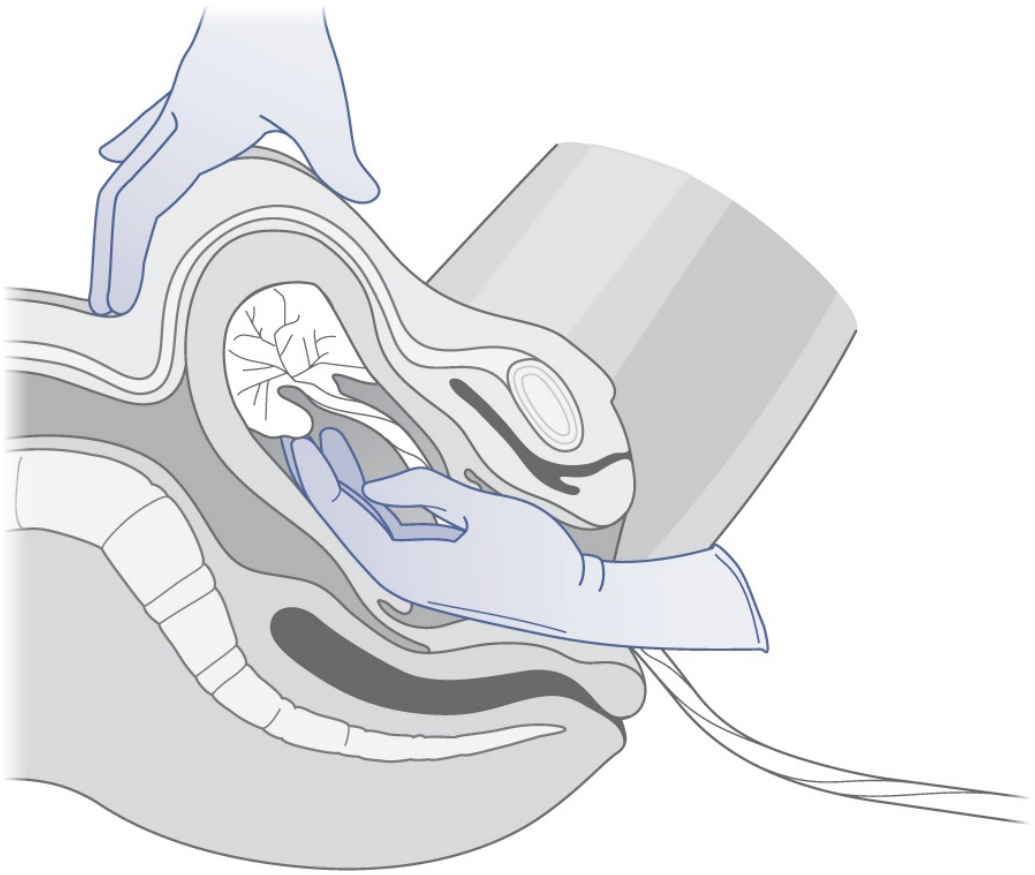

Figure 30C-1 Manual removal of the placenta.

11. Separate the entire placenta before attempting to extract it. If uncertain whether the placenta is totally separated, sweep the uterine wall again, feeling for and separating any remaining areas of attachment. Extraction while a section remains adherent increases the woman's risk of uterine inversion.
12. *Stop* the attempt to remove the placenta if it or its components are adherent. This finding is suggestive of a placental abnormality such as a placenta accreta. Immediate consultation/referral with a physician is required at this point.
13. Extract the placenta slowly after ascertaining that the placenta is not adherent; simultaneously continue to use the external hand to maintain fundal contraction.
14. Membranes may need to be slowly teased out, as described in Appendix 30A.
15. The placenta should be carefully inspected, as described in Appendix 30B. If the placenta does not appear complete, consider performing a uterine exploration to remove any retained tissue (Appendix 30F).
16. Maintain uterine contractility through uterine massage (as needed) and administration of a uterotonic agent. Continue close observation to rule out uterine atony.
17. After the placenta is removed:
    a. If the woman experienced excessive blood loss, assess her response by repeated laboratory evaluations, including hemoglobin or hematocrit values, and the woman's symptoms during the first 24 to 72 hours postpartum. Because tolerance of blood loss is contingent upon many factors, some women will be symptomatic (e.g.,

syncope) at higher levels than others. Management, including blood transfusions, will need to be individualized.

b. Antibiotic therapy is controversial and lacks strong evidence to either support or refute its use. Individualization is indicated, and consultation may be a reasonable action.

c. Document all procedures and the woman's response. Include consultations/referrals if appropriate.

APPENDIX

30D

Initial Management of Uterine Inversion

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

A uterine inversion is an emergency. When a uterine inversion occurs, the risk for postpartum hemorrhage and disseminated intravascular coagulation (DIC) is high. The uterus may need to be repositioned when the woman is under general anesthesia. The most common symptom of uterine inversion is rapid maternal shock. Treatment for shock should be instituted immediately even before symptoms are evident.

1. Inform the nurse or other birth assistant of the diagnosis. Request emergency obstetrician and anesthesiology consultation and additional nursing support. Initiate emergency transfer steps if in an out-of-hospital setting.
2. Have a family member or someone else hold the newborn.
3. Explain to the woman and others in attendance that the uterus is inverted and briefly describe the steps needed to reposition the uterus.
4. Attempt to reposition the uterus immediately. Repositioning will be more successful if attempted as soon as the inversion is recognized and before the lower uterine segment and cervix contract to form a constriction ring.
    a. Do *not* remove the placenta if still attached. Removing the placenta while the uterus is inverted will increase the blood loss and increase the risk of complications.
    b. Manual repositioning is accomplished by placing one entire hand in the vagina.
        i. Initially place the fingertips on the sides of where the uterus has turned on itself so that the inverted fundus is in the palm of the hand (**Figure 30D-1**).

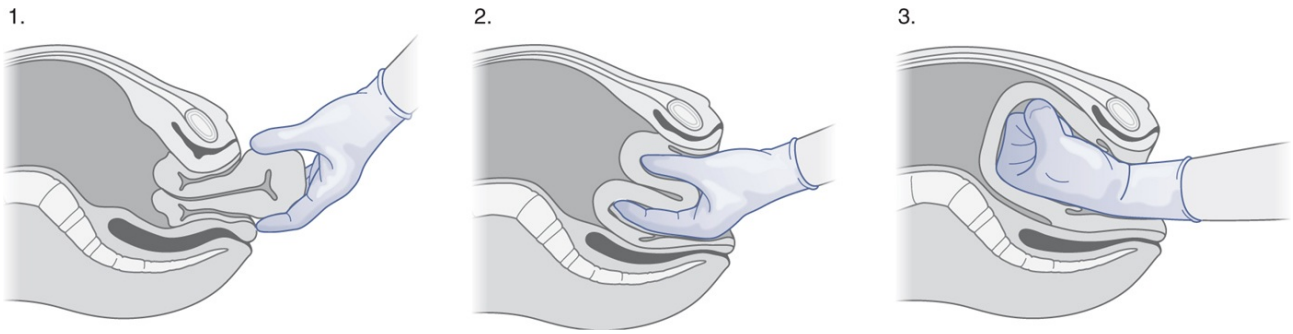

Figure 30D-1 Repositioning uterine inversion.

ii. Apply pressure with the palm of the hand on the fundus and with the fingertips on the uterine walls. Gently walk or slide the fingertips up the uterine walls so the fundus is folded back into its original position. Take care not to puncture or rupture the soft uterine wall.

c. Hold the fundus in place by forming the hand into a fist while waiting for the uterus to contract around the fisted hand. This puts tension on the uterine ligaments, which keeps the uterus in place, and the fist forms a ball that does not allow the fundus to fold in on itself.

d. Keep the hand in the uterus until a consulting physician is present and can take over the maneuver, even if it appears that the inversion has been corrected.

e. Use the abdominal hand to guard the uterus so it is lifted out of the pelvis, above the level of the symphysis, and hold in this position for several minutes.

5. Simultaneously:

a. Have the woman placed in Trendelenburg position.

b. Ask that an intravenous line be placed with a large-bore needle.

c. Discontinue uterotonics until the uterus is replaced.

d. Evaluate for signs of shock.

e. Request operating room and team preparation.

f. Request blood type and cross-match for 2 units of packed red blood cells, or initiate the postpartum hemorrhage protocol if one is in place.

g. Initiate quantitative evaluation of blood loss.

APPENDIX

30E

Management of Immediate Postpartum Hemorrhage

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

Introduction

The management of a woman who is bleeding excessively during or immediately after the third stage of labor depends on the severity of bleeding, whether or not the placenta is expelled, and the available resources. The steps listed in this appendix take the reader through the process of assessing and managing a woman who has just expelled the placenta and whose bleeding is brisk but not life threatening. In practice, management will be customized for the woman and the situation. For example, if the woman is hemorrhaging and the uterus is not firm, bimanual compression may be the indicated first response. Conversely, if the bleeding is less severe, the clinician may check for lacerations before other steps are taken. Similarly, if the placenta is not expelled, the first step will be manual removal of the placenta. Multiple algorithms are available that outline recommended management steps for a woman who is hemorrhaging after birth. The reader is encouraged to know all possible management responses so that the response may be individualized as appropriate. Quantitative blood loss is the preferred method of determining the amount of blood lost during the third stage of labor and during/following a hemorrhage.

Management Steps

1. Maintain or reinstate a calm environment to reduce anxiety and facilitate management.
2. Palpate the woman's uterus, as approximately 80% of immediate postpartum hemorrhages occur secondary to uterine atony. External uterine massage may be the only intervention necessary.
3. If bleeding continues, proceed to the next steps.

4. Explain to the woman and others/family in attendance (with the woman's permission) that vaginal bleeding is excessive and explain the steps needed to resolve the problem.
5. Have a family member or other responsible adult hold the newborn. Alternatively, place the newborn in a safe site under observation.
6. Consult with other members of the healthcare team involved in the birth, including a physician if bleeding continues unabated. At this point, depending on the amount and rate of bleeding, ask for another practitioner to come to the bedside, or if in an out-of-hospital setting, initiate emergency transport.
7. Rule out bleeding from a laceration by efficiently performing an examination of the perineum, vulva, vagina, and cervix. Suture any active bleeding vessels appropriately.
8. If bleeding is not secondary to a laceration or the uterus is atonic, proceed to the next steps.
9. Catheterize the woman's bladder so a full bladder will not interfere with uterine contractility.
10. Order a uterotonic agent, if one was not administered earlier with release of the anterior shoulder of the newborn. Oxytocin (Pitocin) is the most commonly used agent, either 10–40 units in 1000 mL solution administered intravenously at a rapid rate (500 mL/hr), titrated to uterine tone, or 10 units given intramuscularly while intravenous access with a large-bore (usually 18-gauge) needle is initiated. If a uterotonic agent was administered with the birth of the neonate, consider a second agent (e.g., misoprostol [Cytotec], 15-methyl PG-F2a [Hemabate]). See **Table 30-8** for dose, route of administration, and side effects of uterotonic drugs used to treat postpartum hemorrhage. Continue administration of additional uterotonic agents to treat uterine atony.
11. If bleeding continues after the previous steps have been taken and the woman is in an out-of-hospital site, commence with an emergency transfer to a hospital. If the excessive bleeding is controlled quickly, the transfer can be cancelled.
12. If bleeding continues, initiate a second intravenous line with normal saline in preparation for blood transfusion and maintenance of intravascular volume.
13. Verify that a physician has been called; while waiting for emergency services arrival, proceed to the following steps.
14. Initiate *bimanual compression* (**Figure 30E-1**) of the woman's uterus to treat uterine atony.

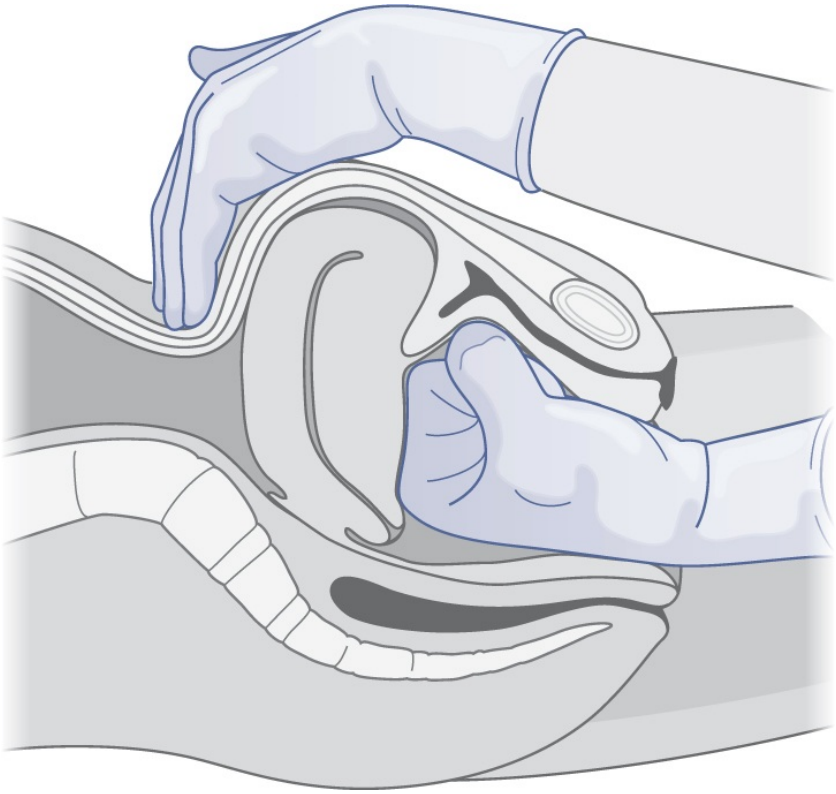

Figure 30E-1 Bimanual compression.

a. Extend the fingers of one hand and squeeze the extended fingers close together, gently insert this hand into the vagina, and close the fingers into a fist as the hand enters the vagina.
b. Position the fist palmar side up into the anterior fornix.
c. Direct pressure to the lower uterine segment/uterine corpus by applying pressure inward and upward against the anterior wall of the uterus.
d. Simultaneously, place the other hand externally on the abdomen and grasp the uterus between the two hands.
e. Apply pressure to the uterus trapped between the two hands by massaging it using pressure directed against the posterior wall of the uterus, primarily in the area of the fundus and corpus of the uterus with the abdominal hand. This compression places direct pressure on the bleeding uterine vessels while stimulating the uterus to contract, an action that will also provide continuous compression.
f. Continue bimanual compression until bleeding is controlled and uterine atony is resolved. The effectiveness of this intervention can be ascertained by momentarily releasing the pressure on the uterus and evaluating uterine consistency and bleeding at that moment.
g. Be aware that atony may seem to be resolved before it actually is, so bimanual compression should not be discontinued until the uterus is firm for several minutes. Removal of the hand and reinsertion increases pain/discomfort and risk of infection.
h. If bimanual compression provides a response but uterine atony does not resolve, continue compression until a physician is present.

15. If in a hospital, the blood bank should be notified and type and cross-match for 2 units prepared.
16. While waiting for a surgeon/obstetrician, engage other essential healthcare team members such as anesthesia personnel, nursing leadership, and other experienced providers available.
17. If retained products of conception are suspected to be the cause of the bleeding, proceed to performing an *intrauterine exploration*. Additional anesthesia or pain management methods may be needed at this point.
18. After bleeding has been controlled, discuss and explain the situation to the woman and her family, as the woman desires.
19. Continue to collect the blood lost and calculate the running total of loss.
20. Assess the woman's response to postpartum hemorrhage by repeat laboratory evaluations, including hemoglobin or hematocrit values, and the woman's symptoms during the first 24 to 72 hours postpartum. Because tolerance of blood loss is contingent upon many factors, some women will be symptomatic (e.g., syncope) at different hemoglobin levels than others. Management, including blood transfusions, will need to be individualized.
21. Antibiotic therapy following uterine exploration is controversial, lacking strong evidence to either support or refute its use. Individualization is indicated, and consultation may be a reasonable action.
22. Document all procedures and the woman's responses. Include any consultations/referrals if appropriate.

APPENDIX

30F

Intrauterine Exploration

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

To perform an intrauterine exploration:

1. Change gloves or put on second pair so that the procedure is as sterile as possible. Gloves of a regular length can be used, but a longer length that overlaps a sterile gown provides more protection from body fluids.
2. Wrap one gauze sponge (e.g., 4 × 4) around two or four fingers, with the thumb stabilizing the gauze against the side of the first finger. The rougher surface of the gauze tends to be an effective modality to pick up placental fragments, ragged membranes, or blood clots. Use only one gauze so that it can easily be accounted for and to minimize the risk of leaving a gauze pad in the uterus or vagina.
3. Place the external hand on the woman's abdomen and grasp her uterus in a similar manner to that performed during bimanual compression, thereby stabilizing the organ.
4. Reduce the diameter of the internal hand by squeezing the extended fingers close together, and gently insert this hand slowly and steadily through the vagina and past the cervix. The entire hand is inserted to facilitate the ability to perform the procedure. Multiple insertions and removals of the hand increase pain and infection risk for the woman, so it is advisable to proceed carefully and intentionally.
5. Using the internal hand, sweep the inside of the uterus with the back of the hand while maintaining contact with the uterine wall so that the entire cavity is explored.
6. Remove the hand slowly from the uterus/vagina and unwrap, assess, and discard the gauze. If uncertain whether all the tissue was removed, repeat the procedure once for any remaining tissue or clots.
7. Maintain uterine contractility through uterine massage and administration of a uterotonic agent. Continue close observation to rule out uterine atony. An extended recovery period may be indicated.
8. Count the number of gauzes used and confirm that none remain in the vagina or uterus.
9. *Stop* the procedure at any time if portions of the placenta are felt to be adherent. This finding is suggestive of a placental abnormality such as a placenta accreta. Immediate

consultation/referral with a physician is required at this point, and preparation of the operating room team is indicated.

APPENDIX

30G

Sudden Postpartum Cardiovascular or Neurologic Emergencies

MAVIS N. SCHORN

© hakkiarslan/iStock/Getty Images Plus/Getty

Physical Examination

- Maternal consciousness
- Vital signs, including temperature
- Oxygenation (O_2 saturation)
- Skin color
- Evaluation of new findings (i.e., bleeding from unexpected sites)
- Continue monitoring uterine tone and vaginal bleeding

Management

- Initiate measures to obtain emergency assistance. If out of the hospital, implement the emergency transport protocol. If in the hospital, call for an emergency response team.
- Initiate a large-bore (18 gauge or larger) intravenous line if not already in place. If already in place, ensure patency, and consider placing a second line.
- Provide calm explanations to the woman and friends or family who are present at her birth.
- Assign someone to provide care to the neonate.
- Administer crystalloid, 0.9% sodium chloride, or lactated Ringer's solution rapidly if the woman is hypotensive.
- Apply oxygen at a 10–12 L/min flow rate via a nonrebreather face mask.
- Obtain blood pressure, pulse, temperature, and oxygen saturation levels frequently. If blood pressure is maintained, do not overload the woman with intravenous fluids—fluid overload can contribute to pulmonary edema.

- Be prepared to initiate cardiopulmonary resuscitation. Prepare for and assist with intubation and ventilation if needed.
- Position the woman in semi-Fowler's position.
- Order arterial blood gases, complete blood count, platelet count, fibrinogen, partial thromboplastin time, blood type and cross-match for 2 units of red blood cells, and chest X ray.
- Catheterize the bladder with an indwelling Foley catheter to drain to a urometer so output is monitored accurately.

CHAPTER

31

Birth in the Home and Birth Center

MARSHA E. JACKSON AND ALICE J. BAILES

Introduction

Birth is profoundly affected by the environment in which it takes place. Ideally, every laboring woman and the team that supports and facilitates her efforts to birth will work together in an environment that is most comfortable and safe for the birthing woman. For many individuals, families, and providers, that safe, comfortable place to give birth is in the home or birth center.

The midwife who works in the home or birth center has an opportunity to develop the hands-on, low-tech skills that are the hallmarks of midwifery. Expertise in and fascination with normal birth make midwives keenly aware of how much they depend on the woman's natural abilities to complete the birth process herself. Although midwives in all settings finely tune their perception and interpersonal skills to amplify a person's abilities to birth, the opportunity to use these skills is increased in the home and birth center environments. The individuals who give birth in out-of-hospital settings are active in creating a network of support that enables them to optimize their health, and to give birth safely, effectively, and with great satisfaction.

As reviewed in the *History of Midwifery in the United States* chapter, midwifery originated in the home. Midwives later added the birth center concept. This chapter describes how the midwife works with those who choose home or birth center as the preferred birth site, and presents evidence-based guidelines for safe practice in these settings. As Varney explained in an earlier edition of this text:

> *If one were to place the control and responsibility assumed by the woman on a continuum, the continuum would stretch from the hospital delivery room at one end to home birth at the other. There are two important breaks in this continuum where power is transferred to the woman. The first break is when birth moves out of the hospital. The second break is when it moves from a freestanding out-of-hospital childbirth center to the home. In each instance the woman moves further away from external regulations and policies that are imposed on her childbirth experience.*[1(p536)]

Background

Until the mid-nineteenth century, healing arts in the United States were home-based, do-it-yourself types of assistance and included a variety of approaches.[2] Pregnant women in the United States anticipated giving birth at home, using their own power, without surgical or medical interventions. Surrounded by women attendants, they were the central figure during a social childbirth.[3,4] Attendants transmitted supportive midwifery skills, through direct empirical experience and apprenticeship.

As the twentieth century dawned, industrialization and urbanization had powerful effects in disrupting social organization and family life, and negatively affecting public health. State census officials began collecting maternal and infant mortality statistics and soon discovered that the U.S. data compared poorly to international data.[5] As midwifery became professionalized, midwives introduced education programs with home-based clinical practices and founded, owned, and staffed practices in both homes and birth centers. The data on the outcomes associated with these midwifery practices revealed good outcomes for midwife-attended births.[6] Nevertheless, a physician-led campaign that promoted physician care in hospitals for childbirth tipped public opinion toward birth in the hospital, where midwives were not permitted to practice.

By the late 1940s and early 1950s, most births in the United States occurred in hospitals. Pain medications sedated women during childbirth, and families were separated during and after the birth process. In the late 1950s and 1960s, a consumer backlash occurred, as many women and families rejected the hospital environment as too confining and disempowering. In turn, consumers, midwives, and some physicians began work to return birth to women's homes.[7-10]

The birth center concept was the culmination of an idea that had been evolving informally for many years. Some midwives may have preferred not to travel, or a laboring woman may not have had a suitable home in which to give birth. In such cases, midwives would designate a separate area of their home or a separate structure in which to attend births. Later, consumers who perceived hospital policies as too restrictive, yet did not want to give birth in their own homes, began to search for an alternative. Midwives were also in search of a place to attend physiologic births. The National Association of Childbearing Centers (NACC), now the American Association of Birth Centers (AABC), was established in 1983; this organization sought to create standards and promote a model facility integrated with the healthcare system, in which "low-tech, high-touch" care could be accessed.[11,12]

Some hospitals today advertise their labor and delivery suite as a birth center or as an alternative birthing center (ABC). These labels can be confusing, as they may be used to refer to both in-hospital and out-of-hospital centers. The birth centers discussed in this chapter are either freestanding facilities or, if within a hospital, are physically separate from the main hospital labor and delivery area. In most cases, they are administratively autonomous units and have specific policies and procedures for operating both the facility and the program for the childbearing families they serve.

Comparison of Home and Birth Center Settings

Both home and birth center practices share philosophical and administrative characteristics. The primary difference between home and birth center births is that birth in a birth center occurs within the professional's territory, to which the woman comes, whereas a home birth is within the woman's territory, to which the midwife goes.[1] Thus, the balance of power in each setting is different.

In the woman's home, the midwife and the assistant are the guests, and the woman is the host. Because the midwife is the one who travels to the woman, labor, birth, and postpartum care are not disturbed by travel that can cause intense discomfort to women in active labor or incur the risk of giving birth en route. When families give birth at home, there is little interruption in family routines for adults as well as for children, and bonding is uninterrupted. When the woman and the newborn are stable and remain undisturbed postpartum, the midwife and the assistant tuck the woman and her newborn into bed and quietly leave the home. Approximately 1% of women give birth at home in the United States. This percentage has been relatively stable since the 1960s, but has increased somewhat in the past 13 years.[13]

The birth center concept is a replicable model that has become a well-recognized choice for families. Birth centers provide an option for families who wish to avoid the hospital, but feel that home birth is not their birthplace of choice or is not available to them. According to the AABC:

> *The birth center is a homelike facility, existing within a healthcare system with a program of care designed in the wellness model of pregnancy and birth. Birth centers are guided by principles of prevention, sensitivity, safety, appropriate medical intervention, and cost-effectiveness. Birth centers provide family-centered care for healthy women before, during, and after normal pregnancy, labor, and birth.*[14](p1)

The Commission for the Accreditation of Birth Centers (CABC) provides a mechanism for external review of birth centers, which in turn gives guidance to professionals planning and practicing in birth centers.[15] Accreditation may enhance both family and practitioner confidence in the birth center choice. There is no comparable agency for home birth.

Safety During Birth in Home and Birth Center Settings

Essential Principles

To preserve safety at home and in the birth center, it is necessary to adhere to some essential principles:[16,17]

1. The woman must be committed to actively engaging in health promotion. When women are healthy and are experiencing normal pregnancy, they increase their chances for good outcomes for labor and birth. Some health problems preclude a home birth or birth center plan.
2. The place of birth must be planned before the onset of labor. Adequate planning for the place of birth includes determination that the woman's health and the pregnancy are within normal limits when labor begins and that family preparations for appropriate support are in place.
3. The attendant must be skilled and able to assess health status appropriately, provide vigilant care, and manage emergency complications should they occur. In addition to assisting with health promotion in the prenatal period, a midwife skilled in caring for women at home or in a birth center is vigilant in observation, communication, data collection, and care. This vigilance identifies both reassuring signs of normalcy and deviations from normal. If problems occur or persist at any time during the prenatal, intrapartum, or postpartum period, the midwife acts to correct the problem or, if necessary, works to stabilize the woman's condition and transfer her to hospital-based care.
4. There is a system in place to access consultation, hospitalization, and emergency transport. Clinical practice guidelines outline indications for consultation and a mechanism for transport to a hospital-based system. The midwife has established relationships with hospital-based practitioners to assure a smooth transition into the hospital should a transfer be indicated.

Outcomes of Birth in Home and Birth Centers

Data collection and research related to the safety and outcomes of home and birth center births have been conducted in many developed nations using varying research methods and populations.[18-21] Studies in the United States have demonstrated that planned home and birth center births for well women who are at term with a singleton fetus in vertex presentation, and who are experiencing a normal pregnancy, are at least as safe as—and, in some cases, safer than—their counterparts who give birth in the hospital.[22,23] Nonetheless, it is important to parse these data carefully. Analysis of this research is complex given the differing populations, risk status, provider type, and study methods included in the various investigations. A detailed bibliography of this body of evidence is included in the Resources section at the end of this chapter.

Maternal outcomes among well women who give birth at home or in a birth center are good, and generally better than the outcomes of women matched for demographic characteristics and

provider type who give birth in a hospital.[22-24] Rates of obstetric interventions and cesarean birth are lower for women who begin their labors planning to give birth in an out-of-hospital setting. Minimizing the use of technology may prevent some complications such as chorioamnionitis and increase the likelihood of normal birth; such technology is intentionally avoided during home and birth center births.[23]

The research findings with regard to newborn outcomes in home and birth center settings vary, and the clinical significance of these findings remains somewhat controversial. For example, studies of birth certificate data from the United States have found the rate of neonatal intensive care unit (NICU) admissions is lower for infants born at home, but the rates of Apgar scores of less than 7 at 5 minutes and early newborn seizures are higher.[22-24,25] Nevertheless, the absolute risk of newborn seizures is less than 1% in all settings; thus, comparing relative risks can convey a message of increased risk that is, in fact, not striking when absolute risks of rare outcomes are evaluated.[26]

Objective analysis of perinatal and neonatal mortality rates is also difficult. Some studies have reported perinatal mortality rates that include fetal deaths and deaths of infants to age 7 days, whereas others have used neonatal mortality rates that include only live births and measure deaths up to 28 days of life. Furthermore, because women with complications are transferred to a hospital and the intended birth site is not always known, newborn outcomes following hospital birth may capture some mother–newborn dyads for whom the family initially planned a home or birth center birth.

Two studies using data from women who planned a birth at home in the United States included an intention-to-treat analysis (i.e., outcome assigned on the basis of the intended site of birth so hospital transfers were included). Snowden et al. found the perinatal mortality rate (stillbirths and perinatal deaths) associated with home birth to be 3.9 per 1000 births.[25] Cheyney et al. reported an intrapartum death rate of 1.30 per 1000 births; early neonatal death rate of 0.41 per 1000 births; and the late neonatal death rate was 0.35 per 1000 births.[27] In the analysis by Snowden et al., the perinatal mortality rate among women with similar characteristics who gave birth in a hospital during the study period was 1.8 per 1000 births.[25] Aggregate data from birth centers in the United States have shown the intrapartum fetal mortality rate to be 0.47 per 1000 births and the neonatal mortality rate to be 0.40 per 1000 births for newborns who were born in a birth center.[23]

Overall, most studies of home birth in the United States and other developed nations have found a small but increased risk of adverse neonatal outcomes associated with home birth, primarily in nulliparous women, although the absolute increase in risk is quite low. The well-conducted, very large Birthplace in England study from the United Kingdom is a good example. For low-risk nulliparous women, home birth was associated with a small increased risk of a composite set of adverse neonatal outcomes: stillbirth after start of care in labor, early neonatal death, neonatal encephalopathy, meconium aspiration syndrome, brachial plexus injury, fractured humerus, or fractured clavicle. This composite measure found a rate of 9 adverse outcomes per 1000 newborns born at home versus 4 adverse outcomes per 1000 newborns born in hospital settings.[18]

In an effort to reach a consensus on the safety of birth outside of hospital settings,

professional organizations continue to discuss their conflicting positions. The American College of Nurse-Midwives (ACNM) states birth at home can be safe for essentially well women who experience an uncomplicated pregnancy and have assistance from a qualified provider.[28,29] The American College of Obstetricians and Gynecologists supports hospitals and birthing centers as the safest sites for birth, but state that their members respect women's right to make an informed choice about their planned birth site.[30] The World Health Organization's position is similar in recommending that women who are medically at low risk can choose home birth if they are attended by a skilled provider and have plans for transfer to a higher level of care if needed.[31]

Essential Elements of Birth Center and Home Birth

Table 31-1 outlines the essential elements for home and birth center births.

Table 31-1	Essential Elements of Birth Center and Home Births
Shared decision making in the client–midwife partnership	
A well-woman experiencing normal pregnancy and promoting her own health	
Clear recognition of the centrality of the birthing woman	
Increased authority for the birthing family and midwife	
Increased privacy available to the laboring woman	
Encouragement of family participation	
Optimal environment for physiologic birth	
Skilled personnel and equipment provided by the midwife	
Complex technologies deliberately kept at a distance	
Safety preserved through links within the community's healthcare system	
Independence in the midwifery practice	
Minimization of bureaucracy	
Home and birth center practices often owned by midwives	

Shared Decision Making

Shared decision making is an inherent component of midwifery care in general, but the process of shared decision making assumes an even more prominent role in the home or birth center setting. Early in the clinical relationship, the midwife introduces the concept of working in a client–midwife partnership, in which each party has a unique set of responsibilities. For more information about shared decision making, see the *Introduction to the Care of Women* chapter.

Authority, Centrality, and Privacy

Women have the right to own their births and to choose those with whom they wish to share their maternity experience. In the small and intimate environments provided in the home or birth center, it is easier for all to perceive the *authority* the woman has to make her choices and expect that her preferences will be honored. In this personalized milieu, distracting events are minimized, increasing the laboring individual's *centrality*. At home or in a birth center, the woman surrounds herself with only the people whom she chooses, meeting her needs for *privacy* or companionship.[32]

With the explicit recognition of her authority in the home and birth center settings, the laboring woman feels a sense of control over the birth's environment, management, and outcome. The woman's confidence in her providers' approach to care grows during the prenatal period, so the only surprises she will encounter in labor are the ones that labor brings. When all members focus only on the woman's centrality, the team may offer their skills, presence, and support for her all-important task of giving birth. They are not distracted as they

work to enhance the woman's comfort and help her use her energy efficiently. The woman's privacy is respected as she creates a team with as few as four persons (the woman and her birth partner, the midwife, and a second qualified practitioner/assistant) or as large as the home or birth center can accommodate.

At home or in a birth center, the environment communicates an expectation of normalcy and promotes physiologic birth. The woman's natural efforts are respected, and all who work with her are dedicated to the concept that birth is normal. It is expected that the woman has the ability to give birth, and that she can do so with physical, social, and psychological support and without the use of complex technology. She is not attached to equipment designed to do the job for her, so she is free to move around and to be in any position she chooses. A walk outdoors can invigorate her, occupy her attention, and promote labor progress. She can use hydrotherapy to promote relaxation. The private labor environment helps the women feel safe. She can make sounds without fear of being overheard by strangers close by. She has her own clothes to wear or not wear as she sees fit. Familiar food and drink that she and her family have provided are available to keep her well nourished and hydrated. Moreover, whether at home or in the birth center, women and their newborns are less likely to encounter pathogenic bacteria and invasive procedures, thereby reducing the risk of nosocomial infection.

In such a setting, emphasis is placed on labor as dynamic, progressing rapidly at some times and slowly at others. Ebbs and flows are normal. Encouraging activity to promote progress and quieting the environment to promote rest are simple tasks. In contrast, in the hospital environment there may be a need to make space available to accommodate other laboring women, so a woman may receive unnecessary interventions to speed labor. At home or in the birth center, attention can be focused on addressing the woman's needs, enabling her to progress or rest, expecting and accommodating plateaus of progress.

Client–Midwife Relationships

In every setting, the relationship between the midwife and the woman is vital. In the home and birth center, it is particularly important to specify the roles that each participant assumes as they share responsibility and work together in a partnership based on mutual trust. Women choose an attendant intentionally, searching for a good fit, and seeking a collaborative, nonhierarchical relationship. Goals and criteria for what is "normal" are clearly delineated. Collectively, along with the woman's support system, all team members share responsibility for both the process of care and the outcome. Working in this way, all promote clear and ongoing communication throughout the maternity cycle.

Midwives who choose home and birth center practice need a clear sense of their own strengths and limitations. They must be comfortable with sharing power and occupying a role that is not central. This requirement challenges midwives to sharpen their communication skills, to be open to discovering how to expand flexibility, and to know how to set and explain evidence-based limits and boundaries. When a woman plans to give birth in the home or the birth center, it is easier for her to see the connections between her actions and the outcomes. Her responsibilities for care are also clear, including recognition that her actions can make a difference.

Home and birth center midwives must be able to determine where philosophical gaps lie between themselves and their clients, and strategize to resolve them. These midwives must also feel comfortable taking a leadership role in the client–midwife partnership. Each midwife must be assertive as she describes the limits of her practice in the home or birth center environments.

Midwife–Consultant Relationships

If variations in the client's health state require consultation, collaboration, or referral, midwives need links to the community's healthcare system that they can activate to benefit the woman. Consultation may be provided by family physicians or obstetricians who are solo practitioners, a group practice, several different practices, or the house staff employed by the hospital. Some certified nurse-midwives (CNMs)/certified midwives (CMs) who attend home and birth center births maintain hospital privileges, facilitating seamless transfer into the hospital when necessary. Other home birth and birth center midwives elect not to have hospital privileges, but maintain consultation relationships with physicians or with hospital-based CNMs/CMs. For the midwife without hospital privileges, establishing a consultation agreement with hospital-based midwifery practices affords a means of access to the hospital, fostering a collegial relationship among midwives. Clients appreciate this arrangement because even if they transfer to the hospital, they still may have their birth attended by a midwife.

Before negotiations with a consulting practice take place, the midwife should write clinical practice guidelines and identify those situations for which consultation, collaboration, or referral would be needed. These guidelines are *not* a supervisory agreement. Many states have passed legislation repealing the requirement that midwives have written collaborative practice agreements with physicians or hospitals. Although writing guidelines is important, midwives and consultants must build a relationship based on open communication, mutual trust, and respect. Most consulting services do not see clients prenatally unless a problem is identified, but women may still want to meet with the consultant and should be encouraged to do so if desired.

Prenatal Care

During prenatal visits, the midwife works to enhance the woman's self-confidence and self-reliance. By giving reassurance regarding the normalcy of pregnancy's changes, and by communicating faith in her ability to give birth, the midwife assists the woman in amplifying her strengths and helps her to compensate for any limitations.

Introduction to the Practice

At the first prenatal visit, the midwife orients the family, introducing them to the services and philosophy of the practice. The midwife, the woman, and her family discuss their needs and explore how the woman envisions getting her needs met as a shared decision-making process. It can be a challenge to have these discussions while maintaining the family's confidence in the birth process. There should be ongoing communication and exploration of concerns throughout the maternity cycle. In this way, self-care is fostered, good decision making takes place, and the woman and her family can become empowered.[32-34] The midwife reviews the strong commitment to health promotion, to keeping birth normal, and to use of nonpharmacologic comfort measures for childbirth. This visit also provides an opportunity for both the woman and midwife to assess their abilities to work together. It is important that adequate time be allotted to cover all of these tasks.

Client Responsibilities During Pregnancy

As part of the introductory visit, the midwife provides an overview of the tasks that the woman will need to undertake to promote optimal health and to maximize the likelihood of having a normal pregnancy, with labor and birth occurring in the birth site she has chosen. Basic health promotion includes good nutrition, adequate rest and exercise, stress reduction, keeping scheduled appointments, and avoiding drugs, alcohol, and smoking. The woman's responsibilities also include assuring the participation of a support partner who will take primary responsibility to be available during pregnancy, labor and birth, and the postpartum period. When small children are to be present at the birth, an adult other than the primary support partner must be available to care for them.

Other responsibilities introduced during the initial visit will be addressed again later in the pregnancy, including breastfeeding preparation, attending childbirth education classes, touring the hospital or birth center, gathering birth supplies, and arranging for the services of a pediatric healthcare provider. Women may also be required to meet with the consultant service during the pregnancy, depending on the practice's guidelines.

Midwife Responsibilities During Pregnancy

The midwife's responsibilities are outlined during the initial visit to clarify the woman's expectations regarding the midwife's role. The midwife explains the concept of working in a client–midwife partnership, with each partner having a separate set of responsibilities. Throughout the maternity cycle, the midwife provides education, guidance, and health care,

with particular emphasis on signs of normalcy and signs of deviation from normal. The midwife makes 24-hour midwifery on-call services available to the woman. Finally, the midwife describes the referral and transport services available. Resources to cover remuneration to both the midwife and the consultant in case of transfer of the woman's care are also important factors to discuss.

Selection of the Birth Site

The advantages and disadvantages of all available birth site options are reviewed in detail during the first prenatal visit so the woman and the midwife can work together in considering the best birth setting, delineating what can and cannot be done in each site. When discussing birth site options, both positive and negative aspects of each site are explored. Fewer than 2% of women in the United States choose to give birth at home or in a birth center.[13] Thus, an understanding of the woman's motivation for her birth choice will enable the midwife and the woman to work together more effectively. The attitudes and concerns of the woman's support partner and/or family should also be included in this discussion.

Influences on choice of birth setting may include the philosophy of the woman, her support network, and the caregivers; preferences regarding technology; feelings about previous birth experiences; societal and family considerations; financial concerns; and the woman's health status.

Safety Criteria and Transfer to Hospital-Based Care

The issue of possible transfer of care if a complication occurs should be addressed at the initial visit and reviewed as needed during subsequent visits. These discussions include a review of the midwife–consultant relationships, hospital privileges, and planned sites for transfer if needed. Problems that can develop during pregnancy, labor, or birth, or in the immediate postpartum period, and their frequency of occurrence should be reviewed with the woman and her family. The importance of self-care and early intervention to promote health should be reemphasized. The midwife reviews the woman's health needs to assure the choice of an appropriate birth site, making the woman aware that some health conditions are best addressed in the hospital. **Table 31-2** lists conditions that may be present preconceptionally or may become evident during pregnancy, which suggest planning birth in a hospital setting is indicated.[28] **Table 31-3** identifies conditions that may develop during labor, birth, and the immediate postpartum period and require transfer to a hospital setting.[28]

Table 31-2 **Conditions That Are Indications for Planned Hospital Birth**[a,b]

Prior Pregnancy Conditions
Previous stillbirth or neonatal death related to an intrapartum event
Primary postpartum hemorrhage requiring additional procedures[c]
Prior cesarean birth
Shoulder dystocia with resulting injury

Current Pregnancy Conditions
Active preterm labor (before 37 0/7 weeks' gestation) or preterm, prelabor rupture of membranes
Essential or gestational hypertension[d]
Evidence of congenital fetal anomalies requiring immediate assessment and/or management by a neonatal specialist
Fetal growth restriction < 5th percentile
Insulin-dependent diabetes or gestational diabetes requiring pharmacologic management
Malpresentation: breech, transverse lie
Need for pharmacologic induction of labor
Post-term pregnancy > 41 6/7 weeks' gestation
Multifetal gestation
Oligohydramnios with additional complicating factors
Polyhydramnios
Placenta previa in the third trimester
Placental abruption
Preeclampsia[e]
Rh isoimmunization
Medical Conditions
Evidence of active infection with hepatitis, human immunodeficiency virus, genital herpes, syphilis, or tuberculosis
Psychiatric conditions that may affect intrapartum care management or maternal or neonatal transition following birth
Substantial medical conditions that have required acute medical supervision during the pregnancy and that could impact the birth, such as cardiac disease, epilepsy, thromboembolic disease, or hemoglobinopathy
Substance use/dependence

[a] This list is not exhaustive.

[b] Other obstetric or medical conditions may occur during pregnancy that warrant consultation, collaboration, or referral to determine the optimal site for the birth. Risk assessment for an individual woman may vary based on her prior medical, surgical, and obstetric history as well as resources available for hospital access within her community. Individual midwifery practice guidelines and/or client and/or midwife discretion will affect shared decision making about the selection of site of birth, and this process will be documented.

[c] Such as Bakri-balloon, dilatation and curettage, transfusion, and manual removal of placenta.

[d] Diagnosis of gestational hypertension is made following two blood pressure recordings > 140/90 mm Hg, taken 4 hours apart, after 20 weeks' gestation in a woman who was previously normotensive.[32]

[e] Diagnosis of preeclampsia is made following two blood pressure recordings > 140/90 mm Hg, taken 4 hours apart, after 20 weeks' gestation in a woman who was previously normotensive and has proteinuria. Dipstick reading of 1+ can be used if other techniques for detecting proteinuria are not available. Diagnosis can be made in minutes if blood pressure is 160/110 mm Hg or greater. Hypertension and thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, and/or cerebral or visual symptoms may be used for the diagnosis in the absence of proteinuria.[32]

Reproduced with permission from American College of Nurse-Midwives. Clinical Bulletin No. 14: midwifery provision of home birth services. *J Midwifery Womens Health*. 2015;61(1):127-133.[28]

Table 31-3 **Intrapartum, Postpartum, and Newborn Conditions That Are Indications for Transfer from Home to a Hospital[a]**

Intrapartum Indications[b]
Malpresentation: breech, transverse lie identified during labor
Development of signs or symptoms of gestational hypertension[c] or preeclampsia[d]
Evidence of chorioamnionitis[e]
Evidence of fetal intolerance of labor or persistent Category II fetal heart tones[f] that are unresponsive to intrauterine resuscitation when birth is not imminent or in the presence of meconium
Need for pharmacologic augmentation of labor
Signs of placental abruption or unexplained increased vaginal bleeding
Postpartum Indications
Management of lacerations beyond the expertise of the attending midwife
Postpartum hemorrhage unresponsive to initial treatments
Retained placenta
Unexplained vaginal bleeding
Newborn Indications
Unstable health status

[a] Other obstetric or medical conditions may occur that warrant consultation, collaboration, or referral to determine the optimal site for the birth. Risk assessment for an individual woman may vary based on her prior medical, surgical, and obstetric history as well as resources available for hospital access within her community. Individual midwifery practice guidelines and/or client and/or midwife discretion will affect shared decision making about the selection of site of birth, and this process will be documented.

[b] When birth is imminent, careful consideration of the potential effect of transport on best practice management must be a priority consideration.

[c] Diagnosis of gestational hypertension is made following two blood pressure recordings > 140/90 mm Hg, taken 4 hours apart, after 20 weeks' gestation in a woman who was previously normotensive.[32]

[d] Diagnosis of preeclampsia is made following two blood pressure recordings > 140/90 mm Hg, taken 4 hours apart, after 20 weeks' gestation in a woman who was previously normotensive and has proteinuria. Dipstick reading of 1+ can be used if other techniques for detecting proteinuria are not available. Diagnosis can be made in minutes if blood pressure is 160/110 mm Hg or greater. Hypertension and thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, and/or cerebral or visual symptoms may be used for the diagnosis in the absence of proteinuria.[32]

[e] Chorioamnionitis is defined clinically as maternal fever > 38°C (> 100.4°F) with maternal tachycardia (> 100 bpm) and/or fetal tachycardia (> 160 bpm).

[f] Guidelines for intermittent auscultation are detailed in American College of Nurse Midwives. Clinical Bulletin No. 13: intermittent auscultation for intrapartum fetal heart rate surveillance. *J Midwifery Womens Health*. 2015;60(5):626-632.

Reproduced with permission from American College of Nurse-Midwives. Clinical Bulletin No. 14. Midwifery provision of home birth services. *J Midwifery Womens Health*. 2015;61(1):127-133.[28]

The midwife's clinical judgment, skills, and resources influence decision making regarding the optimal birth setting for an individual woman. This assessment includes an evaluation of safety for the midwife. If the midwife feels the home is unsafe, the woman does not have documented prenatal care, or hospital resources are geographically too distant, a hospital setting should be recommended.

The midwife has ultimate responsibility for linking into the rest of the maternity care system,

even though some women arrange or lay the groundwork for consultation/hospital services.

Although urgent emergencies may occur in any birth setting, they are rare in the home and in the birth center.[23-25,27] Women need to explore their feelings regarding the possibility of a negative birth outcome regardless of their planned birth setting. They may not be ready to discuss this very sensitive issue in depth at the initial visit. Instead, introducing this subject during the first visit and revisiting it during subsequent prenatal visits is the best way to make sure this topic is fully explored.

Financial Considerations

Financial arrangements must be clear for both self-pay and insured clients, and discussed openly by all responsible parties. A written payment plan should be signed, which includes insurance information and a schedule for payments. Some women seek home and birth center services because they lack financial resources. The economically disadvantaged woman may benefit from the personalized, nonbureaucratic, respectful, one-to-one care associated with midwifery, which she may not encounter elsewhere in the healthcare system. As long as the woman can accomplish the needed preparation for the birth and the pregnancy remains normal, she is a good candidate for a home or birth center birth. Although an out-of-hospital birth may be less expensive if everything remains normal, it may be more expensive than a hospital birth if complications arise. To that end, women should be discouraged from seeking such services purely for financial reasons.

Initial Prenatal Visit

At the initial visit, it is especially important in home and birth center practice for the midwife to assess the client for predictors of normalcy and predictors of deviation from normal that might be evident in the woman's history and physical examination. Records from other healthcare providers should be requested if needed. When this information is obtained, an appropriate birth site may be selected. The woman and the midwife can identify factors that have the potential to develop into problems. Instituting prevention strategies early increases the likelihood that the woman will successfully give birth in her chosen birth site.

Calculation of an Accurate Due Date

Particular attention is paid to calculation of an accurate due date, because for most home and birth center practices there is a 5-week window of safety for the planned birth. A pregnancy is designated at full term from 37 weeks' gestation until 41 6/7 weeks' gestation. Births occurring at less than 37 weeks' gestation or more than 41 6/7 weeks' gestation are considered to be more safely accomplished in the hospital, but occasionally for women who are post-term, the window of safety can be expanded a few days with shared decision making, careful fetal surveillance, and appropriate consultation. When labor occurs before 37 weeks' gestation, the fetal lungs may not be adequately mature. In such a case, the woman whose preterm labor cannot be stopped is referred to the hospital, where staff and technology can give appropriate support to the newborn if needed. Likewise, women who begin labor after 41 6/7 weeks of

pregnancy are at increased risk for meconium staining and variant fetal heart rate patterns during labor, both of which have been implicated as causes of morbidity and mortality.[35]

Return Visits

During each return visit, the woman and the midwife identify reassuring signs of normalcy or identify problems through an interim history, physical examination, and laboratory and adjunctive studies. In the role of educator, the home and birth center midwife teaches the woman about symptoms that could indicate a deviation from normal. In this way, the woman is enabled to continue to take a principal role in early identification of problems, allowing for early intervention. For a woman to remain a candidate for a home or birth center birth, it is especially vital to intervene early, before uncorrectable problems develop. Women should know that if they encounter specific complications, they will lose their opportunity to have the birth they had planned—this knowledge can be a powerful motivator for women to engage in health promotion.

The Family's Preparation for Birth and the Postpartum Period

Planning for birth involves readying the participants and requires considerable time, thought, and energy. More preparation on the part of the family is required when birth occurs at home or in a birth center. **Table 31-4** lists family responsibilities in preparing for childbirth and the postpartum period.

Table 31-4	The Family's Preparation for Birth and Postpartum
Continuing commitment to a jointly created plan of maternity care	
Keeping the midwife informed of any life changes	
Reading material focused on maternity	
Attending childbirth education classes	
Writing an intrapartum birth plan	
Confronting and resolving fears	
Preparing prenatally for breastfeeding and pediatric care	
Preparing invited participants for their responsibilities	
Preparing siblings for their participation	
Paying fees for care and/or conveying insurance information	
Collecting and organizing specified supplies for home birth	
Obtaining and packing supplies to take to the birth center	
Understanding logistics for 24/7 availability of the second qualified practitioner	
Having a clean house	
Arranging for pet safety and care at the time of labor and birth	
Obtaining an infant car seat and assuring proper installation	
Making an accurate, detailed map to the home or checking global positioning system (GPS) accessibility	
Visiting an obstetric consultant, if needed	
Making emergency plans and posting them by each telephone and in the chart	
Having a reliable vehicle available with a full tank of gasoline	

Knowing the route to the hospital or birth center
Arranging doula participation if desired

As the due date nears, childbirth classes help the woman and her primary support partner learn about and focus on the upcoming birth. The classes that are most helpful emphasize the woman's inner strengths and are presented by an instructor who is knowledgeable about home and/or birth center births. The instructor communicates confidence that unmedicated birth is possible, given that few pharmaceutical options are available in the home or birth center. Instead, women will rely on techniques learned in class to enhance comfort and relaxation, to relieve pain, and to augment labor progress. Childbirth classes located in hospitals are often intended as an orientation to the hospital system and prepare the woman for labor and birth in that setting.

Writing a birth plan gives women and their partners an opportunity to discuss what is important to them for their birth. These plans detail preferences about the environment, social interaction, and comfort measures. Women and their partners identify the persons who will be present at the birth, the specific duties they may have, the role of siblings, religious or spiritual observances, and planned events with family and friends. Birth plans also describe coping measures learned from previous births, desired positions for labor and birth, and preferences for privacy and company at various points in labor. Plans for music, photography, and audio and/or video recording may be outlined.

To promote realistic thinking about possible transfer of care, families can be encouraged to write a hospital birth plan in addition to a home or birth center birth plan. This plan focuses on preferences regarding interventions and parental or family contact with the newborn in the presence of necessary medical interventions.

Most home and birth center practices anticipate that women will breastfeed their infants unless there are extenuating circumstances. Breastfeeding is an essential safety factor for women giving birth in homes or birth centers. Breastfeeding helps to keep the uterus contracted, thereby helping to control bleeding postpartum after the birth attendants leave the home or the family is discharged from the birth center. La Leche League and other breastfeeding support groups are invaluable resources for prenatal breastfeeding preparation and support. If breastfeeding problems are encountered, lactation consultants can be very helpful.

Persons who will be present for the birth also require preparation. If children will be present, they also need to be prepared for birth events, including sights and sounds. The children must be cared for by a designated adult other than the birth partner, so the woman and her partner can give their complete attention to managing labor. The designated adult's primary responsibility is attending to the children's needs and the woman's preferences at the time of the birth. This individual's plans for attendance at the birth may change as the children's and/or the woman's needs change; adults designated to care for the children should be prepared to leave the room where the birth is taking place if necessary. The children's support person also commits to caring for the children continuously until the woman and/or her partner return from the hospital if a transfer becomes necessary during or after the birth.

The people attending the birth should be selected carefully. It should be made clear that

people invited to attend the birth may be asked to leave if the woman seems to be distracted by their presence. Some participants may have fears about out-of-hospital births. Addressing their fears before the birth may change attitudes, and their attendance at the birth can be a transformative experience.

For women who plan to give birth in a birth center, bags should be packed and supplies ready by 36 weeks' gestation (**Table 31-5**). Supplies needed for home birth should be organized by 36 weeks' gestation and kept in or close to the room in which the woman intends to give birth (**Table 31-6**). A current electronic or paper copy of the woman's health record should also be available.

Table 31-5	**Family Supplies for a Birth Center Birth**
Nutritious, easy-to-prepare meals and snacks for the family, any support persons, and birth attendants	
At least 3 quarts of juice, energy drink, tea, and broths	
Comfortable clothing to wear during labor and extra clothing to wear home	
Extra pillows	
Music (CDs or electronic device)	
Camera and/or video camera	
Swim trunks/suit and extra towels for partner when water immersion is anticipated	
Entertainment for older children (e.g., books, games, videos)	
Nutritious postpartum meal for the new parents and birth attendants	
Hydrogen peroxide and ammonia for spot removal and laundry	
For the Newborn	
Clean thermometer	
Receiving blankets	
Petroleum jelly	
At least 5 disposable newborn-size diapers and baby wipes	
Baby clothing suitable for the weather	
Car seat, in place, adjusted to fit the newborn

Table 31-6	**Family Supplies for a Home Birth**
Most midwives request that the family assemble and organize supplies by 36 weeks' gestation. Some of the supplies are common household items; others can be purchased through a company that customizes birth kits to the specifications of the midwife or the family.	
Electronic or paper copy of chart to date	
Mattress cover (e.g., plastic drop cloth, shower curtain liner)	
Extra pillows covered with plastic, extra linen	
Soap for hand washing	
Food and fluids for labor, birth, and postpartum for the family, any support persons, and birth attendants	
Flexible straws	
Ice	

Clean towels
Antiseptic solution (e.g., povidone–iodine, benzalkonium chloride)
Wash cloths or 4 × 4 gauze pads
Flashlight with batteries and extra batteries
Mirror
Two-quart size bowls (for placenta)
Bulb syringe
Heating pad
Baby hats
Receiving blankets/soft towels
Thermometer
Petroleum jelly
Measuring tape
Peri pads and underpants
Squeeze bottle for perineal rinse
Disposable waterproof underpads
Baby supplies, including clothes, diapers, wipes, and car seat
Large plastic garbage bags
Plastic freezer bags
Two lightweight plastic containers for emesis
Paper towels
Tissues
Laundry detergent, ammonia, hydrogen peroxide, alcohol
Check photography supplies and charge batteries
Organize audio/music devices and other comfort enhancers

Prenatal Home Visit

A home visit by the midwife and/or the assistant at approximately 36 weeks' gestation can provide assurance that the family is ready for the home or birth center birth. For home birth, a relatively clean house and pet care are obvious responsibilities of the family. Most pets can be present at births without causing any difficulties. The family should prepare a detailed map or ensure global positioning system (GPS) accessibility that can be tested for accuracy when this home visit is made. In addition, the family should make any needed parking arrangements for the midwife and the assistant.

Plans for cord blood preservation, placental encapsulation, or other requested services are discussed during this home visit. If a water birth is planned, the midwife reminds the family to test the hot water tank capacity before labor begins, to assure that all attachments are at hand and functioning properly, and to troubleshoot for any leaks. Information about equipment and safety requirements for water birth are included in the Resources section at the end of this chapter.

An emergency plan and important telephone numbers should be posted in the birthing room and in the woman's chart. The family should make a "practice run" to the backup hospital to

ensure that they know the fastest route, the traffic patterns, the location to park, and the point at which to enter the building should a transfer become necessary. The car that will be used for emergency transportation needs to be in good repair and have adequate fuel to get to the hospital. Having hospital admission forms completed online or a completed paper copy in the chart before labor begins will decrease stress if a transfer to the hospital becomes necessary.

The Intrapartum Period at Home or in the Birth Center

During the intrapartum period, the midwife's role is to be the guardian of the birth environment and the woman's energy to labor and give birth. The woman depends on the midwife's ability to assess for and promote continued normalcy. The midwife's ongoing presence provides physical and psychological labor support, as well as attention to comfort and progress using simple interventions only when necessary. Should any complication occur, the midwife must have the skills needed to manage, stabilize, and in many cases resolve the situation, consulting other resources if indicated. If complications cannot be resolved in the home or birth center setting, the midwife must have a plan to implement a transfer to the hospital.

Personnel and Equipment

Most home and birth center practices employ two intrapartum providers: the primary midwife and a second qualified practitioner or assistant. The assistant may be a second midwife, a registered nurse, an emergency medical technician, or even an individual preparing to ultimately attend a midwifery program. Labor is often long, and to meet the woman's needs, the midwife may need periodic rest. Inclusion of two caregivers assures adequate staff are available to meet the laboring family's needs for support and safety maintenance without compromising privacy. Some families desire the additional services of a doula.

The assistant provides support and technical labor, birth, and postpartum skills. Essential skills for the assistant include evaluation of the woman's physical and emotional needs and status during labor, the ability to monitor fetal and newborn vital signs, and certification in both adult cardiopulmonary resuscitation (CPR) and the Neonatal Resuscitation Program (NRP). In addition, the assistant should be able to provide support with breastfeeding and postpartum care. It is not necessary for the assistant to be a healthcare professional: Childbirth educators, La Leche League leaders, and doulas may also possess the additional skills needed.

The equipment needed to assist with normal birth is simple. Each time the midwife and the assistant attend a birth, they review the individual's chart and birth plan to focus attention on the individual needs. They organize and check the equipment (**Table 31-7**)[32] and review the skills needed to address any specific health issues. **Figure 31-1** shows the equipment needed for newborn resuscitation.

Table 31-7	Midwife Equipment for Birth at Home or in the Birth Center
Essential Supplies	
Current electronic or paper copy of chart available	***Newborn Supplies***
Paper or electronic forms for intrapartum, postpartum, and newborn charting	Heating pad for baby blankets
Birth certificate forms	Bulb syringe
Blood pressure cuff, stethoscope	Cord clamp or tape
Fetoscope/Doppler stethoscope	Baby scale
Gloves (sterile and nonsterile)	Measuring tape
Lubricant (sterile and nonsterile)	Vitamin K

Antiseptic wash
Urinary catheters
Suture with needles
Local anesthetic, syringes, and needles
Urine dipsticks
pH indicator paper
Intravenous fluids: lactated Ringer's and 5% dextrose in Ringer's lactate, normal saline
Intravenous catheters, long intravenous tubing, tape, antiseptic ointment, gauze pads
Blood collecting supplies: tourniquet, tubes, syringes, needles and Vacutainer
Sharps box and mechanism for hazardous waste disposal

Sterile Instruments

Scissors (2 pairs)
Large clamps (Kelly or Rochester-Ochsner)
Needle holder/driver
Ring forceps
Amniohook
Sterile 4 × 4 gauze pads
Erythromycin ophthalmic ointment

Resuscitation Supplies

Light source (e.g., flashlight)
DeLee suction trap or suction machine
Infant positive-pressure resuscitation bag and mask
Pulse oximeter adult/newborn
Laryngeal mask airway
Laryngoscope with infant blade (size 1)
Endotracheal tubes, sizes 3.0 mm and 3.5 mm, with stylets
Epinephrine
Feeding tube #8F and large syringe for stomach aspiration
Oral airways (infant, adult)
Small oxygen tank, oxygen mask and tubing

Postpartum Hemorrhage Control

Injectable oxytocin (Pitocin)
Injectable and oral methylergonovine maleate (Methergine)
Misoprostol tablets (Cytotec)

Extra Supplies

Adult positive-pressure resuscitation bag and mask
Antibiotics and 150-cc normal saline bags for intravenous administration of antibiotics
Camera
Electrolyte replacement drink (e.g., Pedialyte, Gatorade)
Flexible straws
Hot-water bottle or heating pad
Lidocaine jelly for topical use
Massage roller
Slow-cooker pot for hot perineal compresses

Newborn Supplies

Baby footprint stamp
Blood glucose monitoring sticks and/or glucometer
Cotton baby hats
Otoscope/ophthalmoscope

Personal Supplies

Apron or gown
Change of clothes
Protective eyewear
Toilet articles, personal medications
Mirror
Speculum

Sterile Instruments

Allis clamps
Combs for acupressure points
Culturette
Hemostats
Tissue forceps

When labor begins, the family contacts the midwife who is the primary attendant and is responsible for coordinating care. During the initial labor call, the midwife gathers data about how the woman is experiencing her labor, her needs, and her support systems. The midwife, the woman, and her support network review choices and make appropriate management plans, taking into account the woman's perceptions and history. Plans may include a decision for the midwife to meet the woman for additional assessment. Maintaining contact between the midwife and the woman may be all that is necessary during the early phases of labor.

If the woman is comfortable at home and has the support she needs, she may want to continue her normal activities of daily living while emphasizing hydration, nutrition, and increased rest as needed. A variety of food choices should be provided by the family for the laboring woman, guests, and the professional staff. Friends and family may come to help with final preparation and management of other household activities, freeing the woman and her primary support partner to focus on the labor.

A woman planning a home birth can "double-make" her bed to protect the mattress. The bed can be made with a full set of linen and then completely covered with a plastic mattress cover, a drop cloth, or a shower curtain. A clean old sheet is placed on top of the plastic so that the bed may be used as desired for labor or birth. When the birth is completed, it is a simple matter to remove the top sheet and the plastic. Clean linen is then available in place for the woman's comfort postpartum.

The midwife or the assistant can perform the first physical assessment of labor in the woman's home, the birth center, or the midwife's office. The initial assessment should include a review of the prenatal record, a physical examination to assess presentation, vital signs of

the woman and fetus, uterine contractions, and maternal response to labor. If membranes are not ruptured, a pelvic examination might be part of the initial physical assessment to document cervical dilation, verify the presenting part, or provide information that the woman requests.

The time frame in which the midwife should be in close or continuous attendance can vary as labor progresses. As labor becomes active, the midwife and/or the assistant will be present to assess maternal well-being and fetal heart tones using intermittent ausculatation.[36] The midwife or the assistant also may augment the birth partner's support measures, give reassurance, and guide the woman to conserve her energy. The woman is free to move around and assume any position she chooses. The midwife may suggest positions that promote comfort, encourage progress, and maintain fetal well-being.

During the second stage of labor, it is not unusual for the woman to continue to change positions, moving from the bed to other locations within the home or birth center. The midwife must be alert, flexible, and able to anticipate the woman's movements. Sterile instruments should be placed on a portable sterile surface, allowing the midwife to move while following the woman's lead. If the woman is reluctant to change position, the midwife may use persuasive communication to suggest positions that will facilitate the birth.

As the fetal head emerges, the woman and/or her partner might reach down to complete the birth (**Figure 31-2**). Within the first few seconds after birth, the midwife or assistant will do a quick evaluation of newborn well-being, assessing the newborn's muscle tone, cord pulsations, and respiratory effort, and then assign a 1-minute Apgar score. The midwife and the assistant continue frequent newborn assessment for the first hour after birth. The newborn is kept skin-to-skin with the mother and covered with warm dry blankets, supporting newborn thermal regulation. The midwife is responsible for directing the assistant's care and continuing to observe the newborn for a successful transition from intrauterine to extrauterine life.

Figure 31-2 The mother reaches to complete the birth.

It is normal for some newborns to latch on to the woman's breast immediately, whereas other newborns are more interested in exploring the change in their environment—looking, listening, nuzzling, licking, and taking their time to find the nipple and latch on. While the midwife is attentive to the progress of the third stage of labor, the assistant monitors the newborn's vital signs without disturbing family–infant bonding. The newborn can remain skin-to-skin in the birthing woman's arms while the assistant checks the vital signs every 30 minutes, or more frequently as indicated. Welcoming the newborn can take place as the family has planned. Siblings are often present at the birth or they can be invited in when the woman wishes.

Birth of the placenta is usually unhurried. If the woman needs or chooses to do so, she may squat or sit on the toilet to facilitate the completion of the third stage. The midwife may dispose of the placenta through a hazardous waste company. Some families desire to keep their placenta to bury under a plant. Other families may make arrangements for the placenta to be dried and encapsulated, although the latter may be controversial.

The Early Postpartum Period and Follow-Up

The first 2 to 4 hours postpartum is a special time for the new mother, her family, and friends to welcome and bond with the newborn. The midwife and the assistant in the home and birth center setting are participants during this time of welcome. Once it is assured that both maternal and newborn vital signs are within normal limits, and the amount of lochia, uterine position, and uterine consistency indicate the uterus is contracted, the midwife can leave the birthing room, facilitating a period of privacy and continued bonding time for the family. The woman and her newborn are likely to be physically stable after breastfeeding is established. Most often, eye prophylaxis and vitamin K administration are delayed until after this initial period of family bonding. Some families make an informed choice to waive these newborn procedures. Perineal suturing, if necessary, may also be delayed if the woman is not bleeding excessively; alternatively, it may be done immediately, according to the woman's preference.

While bonding continues, the midwife can attend to the usual responsibility of documenting the birth. It is not unusual for the midwife to spend this period actively working at jobs typically accomplished in the hospital by nursing, secretarial, housekeeping, and dietary staff. The midwife and the assistant assure proper nourishment for the woman, help with breastfeeding, assist the woman to shower and void, wash the instruments, and put the birth site in order. Quite often, family and friends who have attended the birth as guests become helpers during this postpartum family time.

As long as the newborn is adapting to life outside the uterus well, the physical examination is usually done after a period of bonding according to the family's preference. The midwife does a complete newborn physical examination, often using a warm, but unplugged heating pad. This examination provides an opportunity for teaching, as it usually takes place in the woman's bed and may be performed in the presence of excited children greeting the new sibling. Family members often participate in weighing, measuring, and dressing the newborn in the midst of friends taking photographs and a great deal of socializing and celebration.

After the midwife departs the home or the family leaves the birth center, it is recommended that the newborn and mother stay close together to aid in temperature stabilization, enhance maternal–newborn communication, and stimulate milk production. A newborn bath may be delayed for the first 24 to 48 hours after birth. The woman and newborn are assessed in the first 2 days either at a home or office visit or via a telephone assessment. Breastfeeding, the developing family relationships, adequacy of help in the home, infant caretaking abilities, and follow-up appointments with the newborn's healthcare provider are assessed at this visit.[1] During the 6-week postpartum recovery period, the family may be seen in the midwife's office to evaluate maternal involution and other maternal, infant, or family needs.

Framework for Clinical Management

Management strategies for selected clinical situations in the home and birth center can be divided into three categories: preventive, non-urgent, and urgent emergency. In-labor transfer rates to hospital-based care for women planning to birth at home or in a birth center range from approximately 7% to 24%.[18,20] The likelihood of transfer depends on multiple factors in addition to maternal or fetal clinical status, including distance to the collaborating hospital and collaborative protocols. Although a small fraction of women transfer to hospital care prior to labor, 84%[23] to 89%[27] of those who begin labor at home or at a birth center ultimately give birth at their preferred site. For the majority of the 10% of women who transfer to a hospital during labor, the reason for the transfer is failure to progress in labor (40%) and desire for pain relief medications or maternal exhaustion (20.5%).[27] Postpartum transfer occurs for approximately 1.5% of women who give birth at home and neonatal transfer occurs for approximately 1% of newborns.[27] Postpartum transfer rates from birth centers are similar, with 2.5% of women requiring transfer postpartum and 2.6% of newborns requiring transfer.[23] Most transports for hospital care are nonemergent. When Stapleton et al. reviewed transfers in a national birth center study (n = 13,030), they found that emergency transfer was required for fewer than 1% of women who gave birth in a birth center.[23]

Preventive management is the first line of defense to maintain safety during any birth. Ideally, health promotion during the antepartum period succeeds in bringing a well woman with a healthy pregnancy to term. Most women who choose home or birth center birth understand that to achieve their goal of giving birth in their preferred site, they must experience a pregnancy free of complications. Safety is most effectively maintained when strategies to promote health are actively implemented. Early identification of deviations from normal may be non-urgent, addressed with consultation and collaboration to resolve the deviation. Urgent emergency situations may require referral in addition to consultation and/or collaborative care. If the midwife determines that more personnel and complex technologies are needed, previously arranged plans are implemented for transfer of care to obtain interventions that are more safely provided within a hospital-based system.[15-23,28] During transfer, the midwife must utilize excellent decision-making and clinical skills, and promote good communication among all parties involved—the midwife, the woman, the family, and the consulting practice. Communication with the clinicians who will receive the woman is enhanced with a verbal report, along with a concise, complete chart that serves as an ambassador for the woman and the referring midwifery service.

Management of Non-Urgent Clinical Situations

Prolonged Labor

Prolonged labor due to maternal exhaustion in nulliparous women is the most common reason for transfer from home or a birth center into the hospital. The midwife's patience and attention to supporting the woman's efficient use of energy during labor are the midwife's most important preventive interventions. Adequate hydration and ingestion of nutritional sources of energy are essential. The midwife may encourage periods of rest when labor ebbs.

When slow progress does become a concern, it must be clearly understood that oxytocin (Pitocin) for the purpose of augmenting labor is not administered in the home or birth center. Exogenous oxytocin can cause tachysystole and variant fetal heart rate patterns that may indicate developing fetal acidemia if persistent. If labor progression cannot be accomplished by means of upright positions, adequate hydration, nutritional support, or nipple stimulation, then a hospital transfer may be indicated.

Sometimes when labor continues without progress, the woman becomes too fatigued to cope with labor pain and strategies for nonpharmacologic pain relief are no longer effective. If the woman's need for pain relief cannot be satisfied by the choices available in the home or birth center, a transfer to the hospital is indicated. A non-urgent transfer may take place in the family car as long as maternal and fetal vital signs are within normal limits. Women transferred for prolonged labor with their first birth can usually complete subsequent births at home or in birth center settings.

Prolonged Rupture of Membranes

In cases of prolonged rupture of the membranes, concern about infection is reduced but not eliminated at home or in the birth center. Pathogenic bacteria are not in abundance as long as the woman is not a carrier of group B *Streptococcus* (GBS), and avoiding vaginal examinations decreases the risk of infection. Nevertheless, monitoring for signs of infection remains critical. Setting a time limit before transfer to the hospital, if necessary, will depend on the midwife's preferences, the woman's preferences, and negotiations with the healthcare system, including consideration of maternity care and neonatal community standards.

Group B *Streptococcus* Colonization

Women who have vaginal colonization with GBS may give birth safely at home or in a birth center. If intravenous antibiotic prophylaxis is indicated, the antibiotic may be administered in these settings. Women who are colonized with GBS should discuss follow-up plans for the neonate's care with their pediatric care provider during the prenatal period. Families can be taught to monitor and record the newborn's vital signs, enabling them to convey information about the newborn's health to the pediatric care provider within 12 to 48 hours after birth.

Meconium Staining

Meconium-stained amniotic fluid does not always indicate a need to transfer the woman to the hospital. If meconium appears at any time after rupture of the membranes, the color, consistency, and amount of the meconium should be evaluated. Notification of the consultant depends on the consultation agreement and the characteristics of the meconium. Amniotic fluid with thick meconium indicates that the woman should be transferred to the hospital before the birth, if there is adequate time to do so safely.

If the fetal heart rate has normal characteristics that do not suggest development of fetal acidemia, and if labor is progressive and well established, proceeding with the home or birth center birth is appropriate. However, a discussion with the woman and her support partner regarding the midwife's assessment, possible consequences of meconium aspiration, and treatment options both in and out of the hospital should always be initiated and documented. A transport decision is made by combining the midwife's clinical judgment, skill and experience with consideration of the family's preferences. If the decision is made to remain at home or in the birth center for the birth, a DeLee suction trap and other resuscitation equipment should be readied.

Vaginal Birth After Cesarean Birth

Women who have experienced a prior cesarean birth may want to avoid having another cesarean. Some women who want to have a vaginal birth after a prior cesarean live in geographic areas where local hospitals do not provide vaginal birth after cesarean (VBAC) services.[37,38]

Both risks and benefits are associated with a trial of labor after cesarean (TOLAC) or an elective repeat cesarean birth (ERCB), as reviewed in the *Pregnancy-Related Conditions* chapter. If the woman has experienced a prior cesarean birth, the decision about which type of birth to have can be a complicated decision for families to make.

In brief, limited data indicate that approximately 87% of women who give birth at home or in a birth center and who have had a previous cesarean birth will experience a vaginal birth—a rate that is higher than the 74% successful VBAC rate among women who plan a VBAC in a hospital setting.[37-39,40] Although the successful VBAC rate may be higher in out-of-hospital settings, women who labor after a prior cesarean birth have an increased risk for uterine rupture and subsequent increase in fetal/neonatal morbidity or mortality.[37-41,42] Cox et al. examined birth outcomes among a large cohort of women who planned to give birth at home to identify differences in maternal and fetal-neonatal outcomes between women with a history of prior cesarean birth (n = 1052) and multiparous women in a comparison group who had not had a prior cesarean birth (n = 12,092).[37] A between groups comparison of neonatal outcomes for the same cohort of women revealed an almost four-fold increase in combined intrapartum and perinatal death in the prior cesarean birth group versus the comparison multiparous group (4.74/1000 births versus 1.24/1000 births; $P \leq 0.05$).[37] Studies of newborn outcomes for women who had a previous cesarean birth and labor at home have also found an increased incidence of newborn seizures (adjusted odds ratio [aOR], 8.53; 95% confidence interval [CI], 2.87–25.4; 0.19% versus 0.02%, respectively) and Apgar scores of less than 7 at 5 minutes (aOR, 1.5; 95% CI, 1.35–1.96; 2.68% versus 4.42%, respectively) when compared to a

similar cohort of newborns of women who gave birth in a hospital setting, although newborns in the hospital setting had higher rates of NICU admission (aOR, 0.40; 95% CI, 0.29–0.57; 1.11% versus 3.10%, respectively).[39]

A previous cesarean birth with no prior vaginal birth is among the conditions associated with the highest perinatal death rates (10.2/1000 pregnancies) following birth at home—a rate that is similar to the perinatal death rates for breech presentation (16.8/1000 pregnancies), twin gestation (14.5/1000 pregnancies), and preeclampsia (16.1/1000 pregnancies).[42] Nevertheless, the absolute risk of perinatal death is less likely for women who have a previous cesarean birth and a prior vaginal birth when compared to the perinatal death rate for nulliparous women (1.27/1000 pregnancies versus 3.43/1000 pregnancies, respectively).[42] Having had one vaginal birth appears to confer significant reduction in the risk for adverse outcomes.

Other studies of women who had a prior cesarean birth and labor at home or at a birth center in the United States have noted an increase in neonatal morbidity and mortality when compared to outcomes of women with a prior cesarean who give birth in a hospital setting.[37-39,41] ACNM and other organizations recommend a hospital as the preferred birth site for women who had a previous cesarean birth.[43]

Management of Urgent Emergency Clinical Situations

Variant Fetal Heart Rate Patterns

Variant fetal heart rate patterns, such as recurrent decelerations or tachycardia, that do not resolve with increased hydration, a change in maternal position, and/or a brief period of oxygen by mask indicate that the fetus is at increased risk for developing metabolic acidemia. A transfer to the hospital by ambulance is indicated in such a case to allow access to the needed personnel and technology to manage the problem if there is time to complete the transfer before the birth occurs. Similarly, if at any point during the labor, the midwife feels a need to monitor the fetus more closely than intermittent use of the fetoscope or Doppler allows, then the woman should be moved to the hospital rather than a fetal monitor moved to the woman. Intrapartum use of electronic fetal monitors is outside the Standards of the American Association of Birth Centers (AABC).

Malpresentation: Breech Presentation

Women diagnosed prenatally with a fetus in breech presentation or other malpresentation should have a shared decision-making discussion about external cephalic version, planned hospitalization for vaginal breech birth, or cesarean birth for breech. Breech presentation at the onset of labor is an indication for hospitalization, given the increased risk for adverse newborn outcomes.[42] Rarely, a woman in labor at home or in the birth center may present with a fetus in breech presentation that was not previously detected. If the birth is imminent, the midwife should manage the breech birth in place, but call 911 for extra personnel and transport resources should they be needed.

Postpartum Hemorrhage

A common fear regarding home or birth center birth is “What if the woman bleeds too much?” The reality is that postpartum hemorrhage requiring transport is rare, with its incidence being reported as between 0.2% and 1%.[23] In research that compared outcomes for a group of women giving birth in the home or a birth center with a low-risk group of women giving birth in the hospital, a greater incidence of hemorrhage was found in the hospital group.[19]

If postpartum bleeding is excessive and attributed to uterine atony, intravenous volume expanders with added oxytocin (Pitocin) can be initiated, methylergonovine maleate (Methergine) can be administered intramuscularly or orally, and/or misoprostol (Cytotec) can be administered orally or per rectum per standard protocols for drug, dosage, and timing. However, if a woman has a prenatal hematocrit of less than 30% or a hemoglobin of less than 10 g/dL, she may be unable to tolerate even a normal postpartum blood loss; in this circumstance, prenatal transfer to hospital-based care may be considered.

If immediate or delayed postpartum blood loss results in symptoms of hypovolemia such as dizziness, weakness, or difficulty in ambulation, transfer to hospital-based care is needed because blood and blood products are not available in home and birth center settings. If the

woman is stabilized at home but subsequently experiences reduced self-care abilities or delayed lactogenesis II, she may require hospitalization for evaluation and treatment. It is important to remember that women who give birth at home or in a birth center will not have continuous professional postpartum support beyond 3 to 12 hours postpartum.

Newborn Complications

"What if the baby doesn't breathe?" is the number one fear that the general population has regarding home and birth center birth. The reality is that resuscitation is rare when a well woman experiences a healthy pregnancy, has an unmedicated and uncomplicated intrapartum course,[44] and has an uncomplicated birth at home or in a birth center. Nevertheless, as noted earlier, Neonatal Resuscitation Program certification is a critical skill for both the midwife and the second qualified practitioner who attend home and birth center births. When a need for resuscitation occurs in these settings, both the woman and the newborn may need medical support at the same time, so having two qualified providers present is essential. In the large majority of cases, the resuscitation equipment and skills provided by home and birth center midwives are usually successful in stimulating the newborn's respiratory effort. If this does not occur, the goal is to stabilize the newborn and provide adequate oxygenation until transport to a neonatal intensive care unit is completed.

Transfer to Hospital-Based Care

If problems require hospital-based care, the midwife becomes the link between the family and the hospital that will provide the necessary intervention that all wished to avoid. Intrapartum transfer is stressful for all concerned—the family, the midwife, and the hospital receiving the family—and good communication among everyone involved is critical. Notifying the receiving providers as far in advance as possible helps the transfer go smoothly and enables the woman to get the care she needs in a timely fashion.[45] Transfer is usually accomplished by car for non-urgent indications. Management of complications that may occur during labor, birth, or the early postpartum period depends on written clinical practice guidelines, characteristics of the woman and her support system, the network of health system support, and the midwife's ability to perform clinically.[28] Other factors that influence decision making may include the CNM's/CM's level of experience, distance to the hospital, and road conditions. The transfer summary is a simple, easy-to-use form that conveys pertinent data to the receiving staff (**Figure 31-3**). It is also a quality management tool that enables accurate statistical collection of practice data.

Name _____

Date	Time	
		Reason for transfer:
		Review with client and family:
		Name of consultant:
		Name of hospital:
		Consultation and plan:
		Transport called (if applicable):
		Arrival of transport vehicle (if applicable):
		Mode of transport:
		Mother: T ____ P ____ R _____ BP ____ Condition _____
		Baby: FHT _____ T _____ P _____ R _____ Condition _____
		Departure from home/birth center (circle one)
		Arrival at hospital/accompanied by:
		Receiving provider:
		Type of intervention:
		Initiation of treatment:
		Birth information: SVD Inst. Asst. C/S Apgar ___/___
		Outcome summary:
		CNM departure from hospital:
		Breastfeeding status:
		Release for hospital records sent:
		Hospital records received:

In most situations, the problem necessitating transfer is identified as it develops over time. Unfortunately, transfers often occur when labor has been long, and both the woman and the midwife are fatigued. When a hospital transfer becomes necessary, women who had planned a

home or birth center birth must cope with two concerns: worrying about their health and/or their fetus/newborn's health, and experiencing the feelings (perhaps grief) associated with the loss of their planned home or birth center birth. The client and her family may be disappointed, and sometimes they may blame the midwife for their difficult situation.

Providing anticipatory guidance during prenatal visits can reduce the family's distress if transport becomes a reality. Reminding families late in pregnancy of the possibility that transfer could be necessary, reviewing practice statistics, and describing actual transport experiences may be helpful. Discussion may include a review of not only the decision-making process, but also consultation services, the trip to the hospital, and the admission process. Women need help to understand that if they are going to the hospital, they are going because they need the technical interventions.

During the process of shared decision making at the first visit, and again around 36 weeks' gestation, women should be made aware of the possibility that their fetus/newborn could be injured or die during the birth process regardless of their chosen birth setting. Although most people hesitate to focus on this frightening issue, women need to ask themselves what they would do and how they would cope. They also need to explore how they would respond to family or friends who may not have been supportive of their decision to give birth away from a hospital. In such circumstances, the midwife needs to be prepared to offer additional support and counseling for the woman and her family. Some women, as well as the practitioners who serve them, may benefit from professional counseling to process unexpected outcomes.

Promoting a Smooth Transfer of Care

Best practice guidelines for transferring from a planned home birth to a hospital setting have been developed by the Home Birth Summit.[45] The guidelines include model practices for midwives and receiving hospital staff as well as recommendations for policy development.[45]

Management dilemmas may occur particularly if the woman's birth plan or desires conflict with accepted medical community standards. It may be difficult to convince a consultant to implement a plan that may be safe, but unpopular in the medical community. Both the midwife and the consultant may be caught in the middle. Families may pressure their midwife to continue care despite complications that arise during the labor or birth. This conundrum has the potential to threaten the relationship with the consultant, and it can create a climate of disrespect at the hospital that could cause clinical harm for that family. Such a choice also has the potential to negatively affect the home or birth center practice, creating barriers for clients and the practitioners who serve them and, therefore, adversely affecting future birth options in the community. Many times a midwife may be tempted to be led by the heart instead of the head. Wish management does not work. Learning to say "no" is not just important—it is critical. Midwives must be brutally honest with themselves and not be pressured by clients to practice outside of their clinical practice guidelines and circle of safety. Care must be taken not to jeopardize the entire practice for one client.

Business Aspects of Home and Birth Center Settings

The legal status of home birth and birth center settings varies in different states within the United States. In a few states, it is illegal for midwives to attend home births. Furthermore, regulatory requirements that must be met by midwives who attend home births vary by state. Birth center regulation is also inconsistent from state to state. Midwives practicing in the United States are encouraged to investigate the legal requirements for home birth and birth center operation in the states in which they live and practice. ACNM has staff specializing in professional services and legislative liaisons to keep members aware of practice and political issues. AABC also has staff who assist midwives who plan to open and operate birth centers. To break down barriers, safeguard the profession, and protect the healthcare rights of women and their families, home and birth center midwives have to be both alert and proactive.

All midwifery practices need to address business and regulatory issues. Many of the same professional and legal documents that are necessary when starting a hospital practice are also necessary for a home or birth center practice. Birth center and home birth practices are often midwifery owned and operated. A self-employed independent midwife has more control over clinical, business, and administrative decisions. These practices tend to be small, minimizing bureaucracy and simplifying communication and policy. Such a small organization is more responsive to the needs of the woman, her family, and the midwife when compared to a larger institution. On the downside, there is much more responsibility, time involved, and financial risk in self-employment.[32]

Administrative support is helpful for a home or birth center practice, so that the midwife can continue providing clinical services. The person in charge of billing and collections is key to the practice's financial survival. His or her interpersonal skills and commitment to the practice help keep the service financially sound. Salaries for clinical staff should amount to approximately 50% of the income generated by the practice. Even in established practices, it is not uncommon for home birth or birth center midwives to have lower salaries than their hospital-based colleagues.

Many home birth and birth center midwives are participating providers on health insurance panels, and are reimbursed by Medicaid. Some insurance companies require accreditation through the Commission for Accreditation of Birth Centers for birth center–based midwives to become participating providers. ACNM has developed materials to help midwives develop business and negotiation skills.

Financial arrangements with consulting practices should be clear. Consultants may decide not to charge a consultation fee to the midwife for providing services, but rather charge the woman only for services actually rendered. By assuring that the woman pays the consulting practice promptly, the midwife fosters a good consultation relationship. Sometimes when consultants serve home and birth center practices, those consultants may benefit from referrals not only from the midwifery practice, but also from client networks and sympathetic childbirth educators. Conversely, hospital-based colleagues may refuse cross-coverage for the consultants.

A system for data collection and analysis should be put in place before a practice opens. Accurate data collection and analysis facilitates evaluation, quality management, validation of

effective practice, peer review, and research. Practice data should be collected regularly and analyzed at least annually. ACNM, AABC, and Midwives Alliance of North America (MANA) have web-based data collection applications. When presented clearly and succinctly, statistics can also serve as a public relations tool conveying important information to families about outcomes and transfers.

Midwives working in home and birth center practices need to be astutely aware of who wields power. These midwives are practicing outside of the mainstream maternity system. Although these midwives work with less bureaucracy and more clinical freedom, their practice is subject to increased scrutiny and they lack the protective institutional layer that a hospital may provide. ACNM has staff specializing in professional services and legislative liaisons to keep members aware of practice and political issues. To break down barriers, safeguard the profession, and protect the healthcare rights of women and their families, home and birth center midwives have to be both alert and proactive.

Conclusion

Midwives have increased access to the important resources of time, place, and social interaction when working in the home or birth center environment, and can promote authority, centrality, and privacy for the women they attend. In the hospital, the staff may become inured to and unconscious of interruptions:

> *Studies found that a woman with a low risk delivery giving birth to her first child in a teaching hospital could be attended by as many as 16 people during 6 hours of labor and still be left alone for most of the time. Routine, though unfamiliar, procedures, the presence of strangers, and being left alone during labor and/or delivery caused stress, and stress can interfere with the course of birth by prolonging it.*[31](p10)

As long as the birth remains normal, midwives limit their role to helping the woman be comfortable, validating the efforts the woman makes to give birth, and, at times, augmenting and redirecting the partner's supportive efforts.

Within the home and birth center environment, continuity of care takes on a new meaning for the midwife. Midwives have more freedom to offer one-to-one care and to be a continuous presence during labor. The midwife carefully selects interventions and utilizes them only when the woman needs them and without interrupting the flow of labor. Being aware of and encouraging changes in place, time, and social interactions are special tasks of the midwife in the home and birth center settings. In these small and personalized environments, midwives maximize opportunities to practice "the art of doing nothing well."[46]

PART VI

Postpartum

CHERYL TATANO BECK

A wealth of knowledge is readily available in this postpartum section for midwives to assist them in providing optimal care to new mothers. The *Anatomy and Physiology of Postpartum* chapter clearly identifies the complex processes a woman's body goes through to achieve physiologic adaptations after giving birth. Every system is involved in restoring a woman's body to its nonpregnant state: cardiovascular, hematologic, respiratory, renal, hepatic, gastrointestinal, musculoskeletal, integument, metabolism, and endocrine. The comprehensive material in this chapter provides midwives with an excellent foundation to provide optimal postpartum care—the topic that is the focus of the *Postpartum Care* chapter. In this chapter, postpartum care is addressed in an extremely organized progression, beginning with the first hour after birth, moving to the initial postpartum period (first 72 hours), and finally in the mid-postpartum period (from discharge to 6 weeks after birth). The *Postpartum Complications* chapter then provides midwives with up-to-date vital information on the diagnosis and treatment of an array of complications that women may experience after giving birth, such as endometritis, preeclampsia/eclampsia, secondary postpartum hemorrhage, and thrombophlebitis. The last chapter in this section, *Breastfeeding and the Mother–Newborn Dyad*, describes the health benefits for breastfeeding women and infants, barriers and facilitators of breastfeeding, contraindications, pharmaceuticals and breastfeeding, a systematic assessment, and problems related to breastfeeding.

As noted at the very beginning of this *Postpartum* section, a mother's physical well-being can influence her mental well-being. In the postpartum period, women's physical and mental well-being are intricately intertwined. Although perinatal mental health disorders are also addressed in the *Mental Health Conditions* chapter to provide a comprehensive summary of the mental health care provided by midwives, this topic is an especially critical consideration during care of women in the postpartum period.

Over the past few decades, postpartum depression has become more widely recognized as a perinatal mental health disorder. Nevertheless, traumatic childbirth and the post-traumatic

stress disorder (PTSD) that can develop as a result of such trauma are all too often overlooked. An estimated 45% of postpartum women have reported experiencing a traumatic birth.[1] In addition, in a recent meta-analysis Yildiz et al. reported the mean prevalence rate of PTSD related to birth trauma as 4.0% in community samples and 18.5% in high-risk samples.[2] Just as in the general population, comorbidity of depression and PTSD can exist in women during the postpartum period. The physical complications addressed in this section certainly should be considered in addition to the impact on women's mental health outcomes as described in the *Mental Health Conditions* chapter.

Furthermore, the relationship between postpartum complications and mental health outcomes is complex. In the Listening to Mothers II U.S. national survey, the presence of more physical problems since birth was significantly related to elevated post-traumatic stress symptoms in mothers.[3] Postpartum complications and distressing symptoms are strongly associated with PTSD and depression.

It may not be readily apparent to a midwife that a woman perceives her birth to have been traumatic. Just like beauty, traumatic childbirth is in the eye of the beholder.[4] How a woman perceives her birth may be quite different than how that birth is viewed by the midwife who was present at the birth. It is critical that midwives identity as soon as possible those mothers who are struggling with the aftermath of birth trauma so that interventions can be started quickly. Traumatic childbirth can have long-term chronic consequences. The minutes or hours during the birthing process that a woman perceives as traumatic can be likened to a pebble dropped into the water, resulting in ripples spreading out.[5] Some of these ripples resulting from traumatic childbirth can negatively impact mothers' breastfeeding experiences, the anniversary of their birth trauma, and their subsequent births.

Traumatic births can impact not only the women who give birth, but also the midwives who care for them. There can be a cost to clinicians who care for patients who have been traumatized. This so-called secondary traumatic stress has been well documented in midwives.[6] A birth affects every individual present, and those effects can be lifelong. As we care for women during the postpartum period, we also need to remember to care for ourselves.

Introduction

Physiologically, the postpartum period begins with expulsion of the placenta and continues through to the involution of the uterus and return of other reproductive organs to a nonpregnant state. Postpartum is not a return to the prepregnancy state because pregnancy itself has some lasting effects on a woman's body.

Classically, the postpartum period is considered to last between 6 and 8 weeks. This time period is not sharply delineated, however, and varies among women. Among breastfeeding women, the anatomy and physiology of the mammary glands will continue to be different than in nonpregnant, nonlactating women for the duration of lactation and beyond.

A woman's ability to complete the important tasks of bonding and caring for her new infant(s)—or, in the case of a stillbirth or other loss, the task of grieving and healing—are affected to a significant degree by her physical well-being. Her physical well-being can also influence her risk for developing postpartum depression, post-traumatic stress disorder, or another perinatal mood disorder.

Anatomy and Physiology of Lactation

Ramsay's ultrasound studies of lactating breasts "in action" have profoundly changed current knowledge of the process of milk production and release.[1,2] The parenchyma includes the milk ducts—structures that have been described as "tangled tree roots." Random and intertwined, the milk ducts often intersect as they reach the nipple/areolar complex. The 9 to 10 ducts open onto the surface of the nipple and the lobular alveolar structure. The presence of "lactiferous sinuses" where the ducts terminate under the nipple are no longer considered to be distinct anatomic structures. The stroma includes the connective tissue, fat (adipose) tissue, blood vessels, lymphatics, and Cooper's ligaments. The glandular tissues (lactocytes, alveoli, and supporting structures) where the milk is formed are interspersed throughout the breast, with more than 65% of the glandular tissues being located in a 30-mm radius from the base of the nipple.[1] During lactation, the breast weighs an average of 600–800 grams.

The functional milk-making unit is the alveolus. The lactocytes—that is, the alveolar epithelial cells—convert nutrients from the maternal circulation into various milk components and secrete milk into the lumen of the alveolar sac (**Figure 32-1**). The alveoli are surrounded by myoepithelial cells that contract under the influence of oxytocin, causing milk to be released into the ductules and ducts and to move through pores toward the nipple. The Montgomery glands just under the areola secrete volatile compounds that elicit specific infant behaviors, including increased sleepiness, head turning, and appetite response; the secretion of these compounds has been proposed as one of the stimuli that promote the so-called breast crawl, which refers to the observation that the newborn may spontaneously crawl toward the breast after birth if placed skin-to-skin on the mother's abdomen and chest.[3]

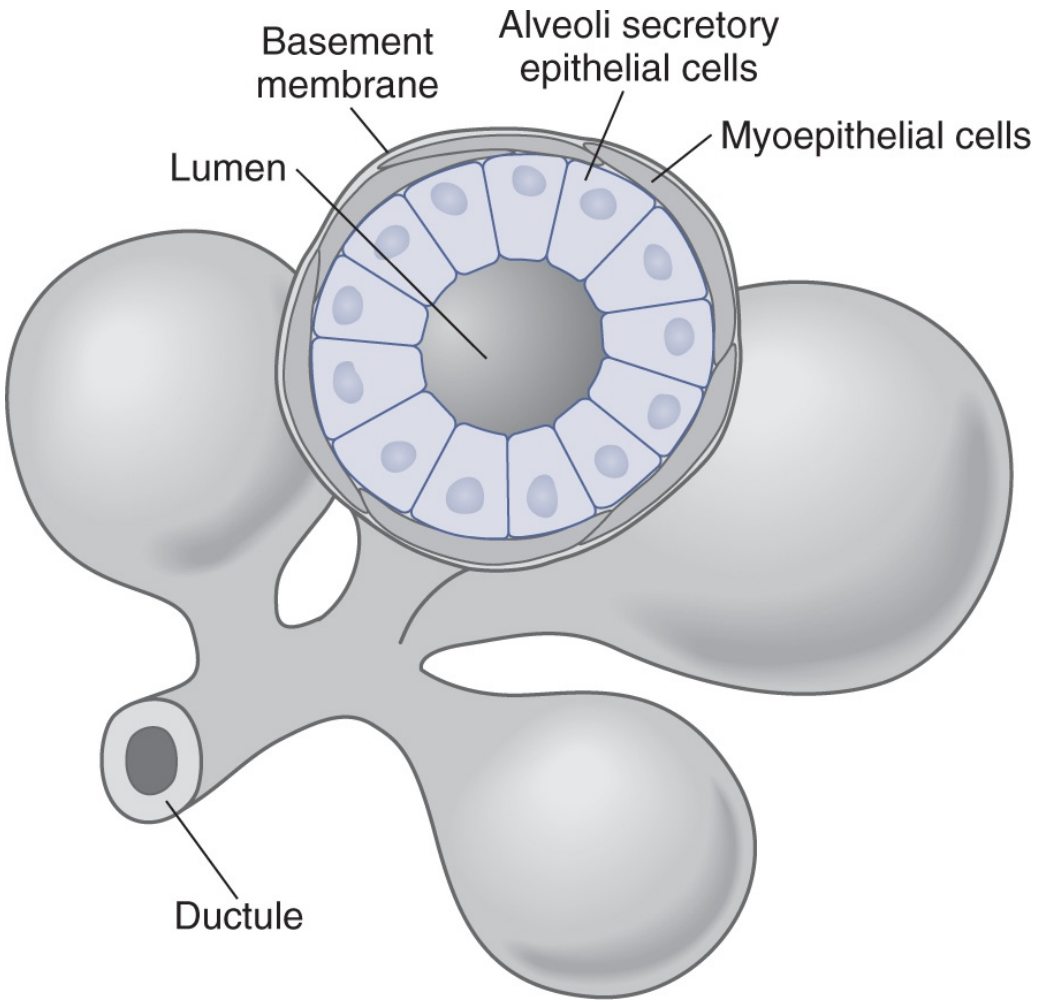

Figure 32-1 Anatomy of the alveoli of the breast.

Lactogenesis

Lactogenesis, which refers to the ability to secrete milk, occurs in four stages (**Table 32-1**). *Lactogenesis I* (secretory initiation) starts during the second half of pregnancy, whereas *lactogenesis II* (secretory activation) occurs in the first postpartum days. *Lactogenesis III* refers to the time when lactation is fully established. *Lactogenesis IV* refers to the mammary gland involution that occurs when breastfeeding ceases.

Table 32-1 Stages of Lactogenesis

Stage	Description	When This Stage Occurs
Lactogenesis I	Cytologic and enzymatic differentiation of alveolar cells; uptake of the substrates for milk begins; colostrum production begins with small fat droplets and proteins.	Begins at approximately 16 weeks' gestation and continues through a few days or even weeks after birth.
Lactogenesis II	Lactose secretion begins and fluid volume increases. Colostrum is essentially diluted by lactose and fluids, becoming "mature" milk.	Occurs approximately 30 to 72 hours postpartum; may be delayed as long as 96 hours after cesarean birth.

Lactogenesis III	Ongoing copious secretion of milk in response to milk removal from the breast by the baby or other means.	Ongoing until weaning and involution.
Lactogenesis IV	Involution of mammary gland and apoptosis of alveolar cells.	Begins when milk removal from the breast diminishes or ends. Some milk may be produced for many weeks or longer after overt production ends.

Lactogenesis I: Development During Pregnancy

By the end of the first trimester, the alveoli epithelial cells (lactocytes) begin secreting proteins and fat (colostrum), placental lactogen, progesterone, estrogen, and prolactin. In the second and third trimesters, the duct system expands and the number and activity of the lobules increase. Veins become increasingly visible on the skin surface of the breast, and women may observe some colostrum leaking from their nipples. By 16 to 18 weeks' gestation, colostrum secretion has begun in preparation for the subsequent onset of copious secretion of milk. Patterns of breast growth during pregnancy vary, and are unrelated to the woman's nutritional status.

Lactogenesis II: Onset of Copious Milk Production

The sudden drop in the plasma progesterone level that occurs once the placenta is expelled triggers the second stage of lactogenesis, which features the onset of copious milk secretion ("milk coming in") and the subsequent delivery of milk to the infant. The lactose secretion in the lactocytes, in combination with osmosis of fluid from the interstitial spaces, causes milk volume to rapidly increase, beginning approximately 30–40 hours after birth.

Lactogenesis II involves both milk synthesis and milk ejection/release (or milk production), with at least two different hormones working in tandem to coordinate these functions. Suckling stimulates the secretion of prolactin by the anterior pituitary. Plasma concentrations of prolactin increase rapidly once suckling starts. The increased prolactin, in turn, initiates milk secretion by the alveolar cells. Suckling also causes the posterior pituitary to release oxytocin, which causes the myoepithelial cells to contract, ejecting the milk from the alveoli and lobules into the ducts.

Oxytocin plays many complex roles in women. It has been called the "tend and befriend" hormone because oxytocin is associated with a calming effect on the lactating woman and infant, stabilization of maternal blood pressure, lower cortisol levels, increase in trust and facial recognition, and decrease in anxiety and aggressive behaviors.[4-6]

Several risk factors may lead to delayed onset of lactogenesis II beyond 72 hours postpartum, including obesity, diabetes, polycystic ovary syndrome, and other biologic conditions that are associated with increased androgen levels.[7-12] Delayed onset of lactogenesis II is also associated with cesarean birth, retained placental fragments, ovarian theca lutein cysts, hypothyroidism, certain types of breast surgery, and severe maternal anemia.[9] The actual etiology of delayed lactogenesis II in women with these conditions is not fully understood and may be multifactorial. For example, women with obesity are at higher risk

for interventions that delay lactogenesis, such as cesarean birth.[8]

Although infant factors such as prematurity or newborn illness that disallows early suckling can negatively affect the normal onset of lactogenesis II, early milk expression (within 1–2 hours after birth) can ameliorate the situation and provide nutrition for the infant.[13] Newborns with an ineffective or weak suck, palate abnormalities, tongue-tie, and congenital heart defects may not be able to effectively remove colostrum; when the infant has any of these conditions, expression of milk should begin within the first 1–2 hours to support normal lactogenesis and milk intake by the infant.[6-8]

Lactogenesis III: Ongoing Milk Synthesis

Lactogenesis III, or galactopoiesis, is the ongoing maintenance of milk production, which includes a switch to autocrine or local control of lactation once lactation is fully established. The mechanism is as follows: Nipple stimulation via infant suckling triggers prolactin release from the anterior pituitary and stimulates the hypothalamus to produce oxytocin. The oxytocin is released from the posterior pituitary.[14] Prolactin stimulates the lactocytes to produce milk, and oxytocin stimulates contraction of the myoepithelial cells surrounding the alveoli, which causes milk ejection into the lactiferous ducts (**Figure 32-2**). Oxytocin is also released through sensory pathways when the mother sees, feels, touches, smells, or hears stimuli that remind her of the infant and breastfeeding.[15]

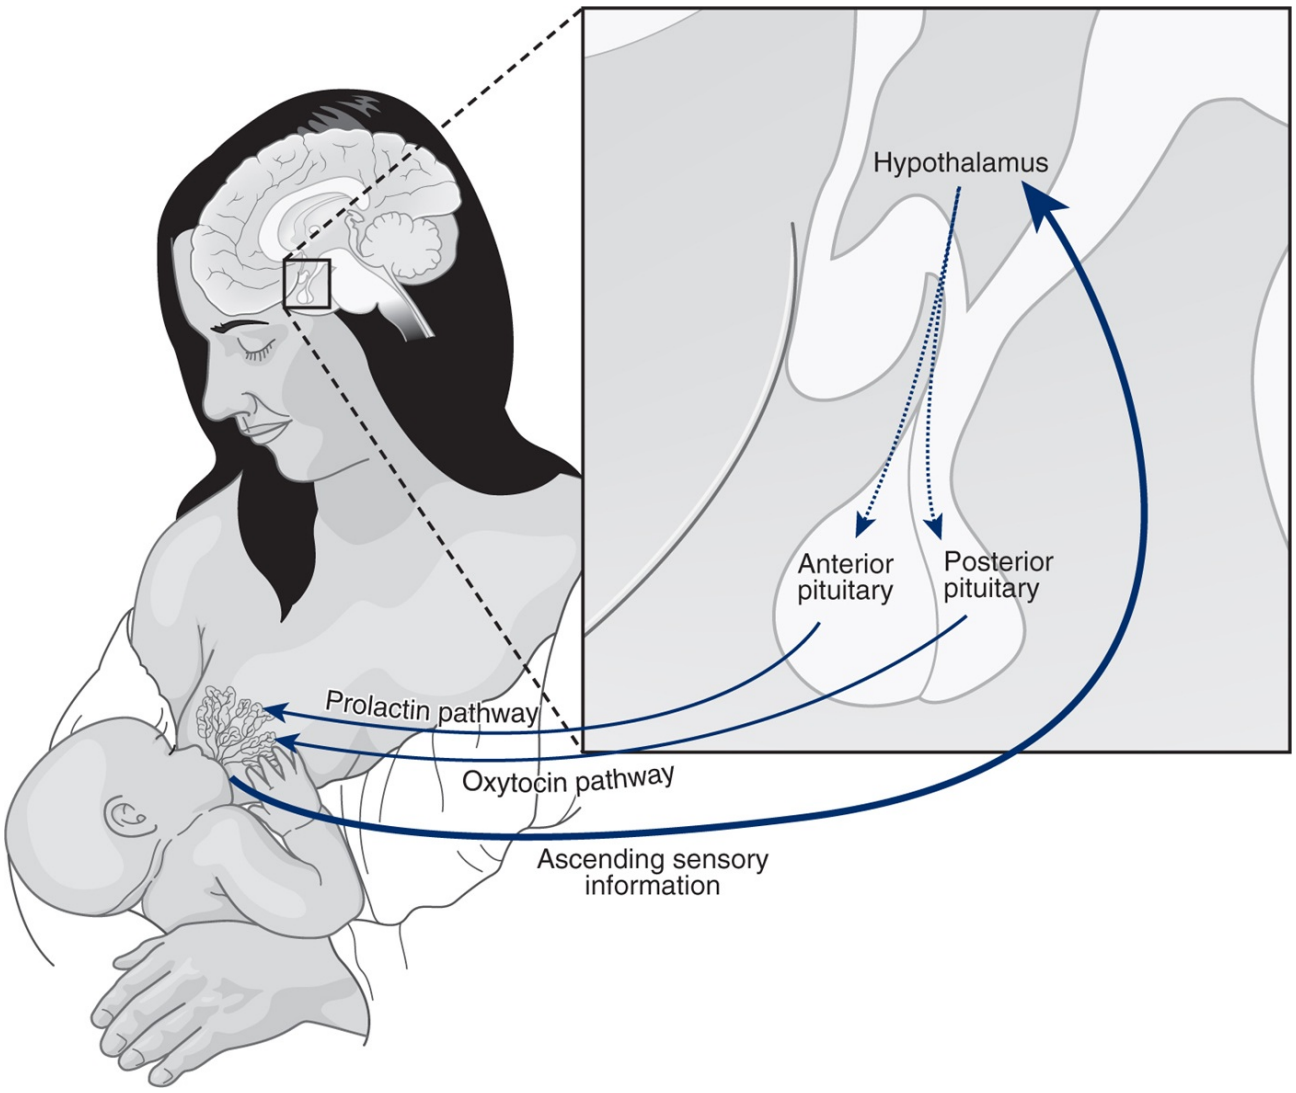

Figure 32-2 Autocrine control of lactation: Infant suckling triggers a nerve impulse that terminates in the hypothalamus. The hypothalamus then (1) manufactures oxytocin and signals the anterior pituitary to release oxytocin and (2) signals the anterior pituitary to release prolactin. Oxytocin is released first and thus the myometrial cells around the alveoli contract and eject premade milk. Prolactin initiates formation of breast milk.

In addition, milk removal stimulates milk synthesis. If milk is not removed from the breast, secretion first slows and then ceases over a period of days.[16] When the milk is not removed, inflammatory pressure causes synthesis and release of a milk protein known as the feedback inhibitor of lactation. This protein downregulates the cell surface prolactin receptors on the lactocytes.[17] In this way, the rate of milk synthesis and the total daily amount of milk produced are closely related to the degree of "emptiness" of the breast, such that milk production varies during the day and night, and from one breast to the other.[18]

The composition of breast milk is one of the more fascinating aspects of this biology, as it varies according to the individual infant's needs. The primary components of breast milk are lactose, oligosaccharides, fats, proteins, minerals, and other bioactive agents such as immune globulins that provide passive immunization. These compounds have multiple functions in addition to providing nutrition. For example, breast milk has bacteriostatic, anti-inflammatory,

and immune-modulating properties in the infant's intestine. Likewise, breast milk stimulates gastrointestinal motility and enhances the maturity of the infant's intestinal tract. Other components of breast milk include neutrophils, lymphocytes, epithelial cells, and macrophages. The macrophages are capable of pinocytosis and chemotaxis, while the lymphocytes direct some immune reactions and development of cell-mediated immunity in the infant.

In brief, breastfeeding has important short-term and substantial long-term benefits for the health of the newborn and infant. Some of these benefits reflect physiologic actions of breast milk, whereas others may be more likely the indirect effects of the maternal–infant interactions. The interested reader is referred to recent reviews, [19-27] and the *Breastfeeding and the Mother–Newborn Dyad* chapter for more in-depth reviews of the benefits of breastfeeding.

Lactogenesis IV: Involution

The process of mammary involution occurs after lactation ceases. Most of the anatomic studies of mammary involution have been performed on mice, so the exact chain of physiologic events that occur in humans is not definitively known.[28] When the infant no longer suckles at the breast, prolactin levels fall in the mother and the effects of prolactin on breast milk production end. The early stages of involution appear to be reversible if suckling resumes. Otherwise, the mammary gland involutes, or regresses through the process of mammary epithelial cell apoptosis (cell self-destruction). Any remaining secretion is absorbed, and adipose tissue from the lactocytes is redeposited within the breast. In most cases, involution takes approximately 6 weeks after milk removal ceases, although the human breast never fully returns to a prepregnant condition.[28]

Gradual weaning invokes a different process of inhibition of lactation and mammary involution that does not involve acute milk stasis, wherein a progressive autocrine inhibition of milk production occurs in response to gradually decreased intake by the infant.[28] Regardless of whether a woman breastfeeds her child, some of the mammary epithelium that was produced during pregnancy is retained. The breasts, therefore, never return to their prepregnant state.

Reproductive Organ Involution

Immediately following birth, the uterus is approximately 20 centimeters in length, weighs approximately 1 kg, and is in a retroverted position.[29] The uterine fundus can be palpated as a firm mass in the abdominal midline several centimeters below the umbilicus in the first hours after birth. In the first few days postpartum, the uterus lies in a slightly retroverted position that "drapes" over the sacral promontory, and is easily palpable in the abdomen.[30] As the uterus contracts further, it undergoes a rotation of 100–180° along the axis of the internal os and assumes an upright position by postpartum day 7.[30] By the end of the first week postpartum, the uterus weighs approximately 500 grams and may still be palpable above the symphysis pubis. By 10 to 14 days postpartum, the uterus weighs approximately 300 grams; at this point, it has typically taken on its nonpregnant anatomic position in the pelvis, which in most women is in an anteverted inclination, and is no longer able to be palpated abdominally (**Figure 32-3**).

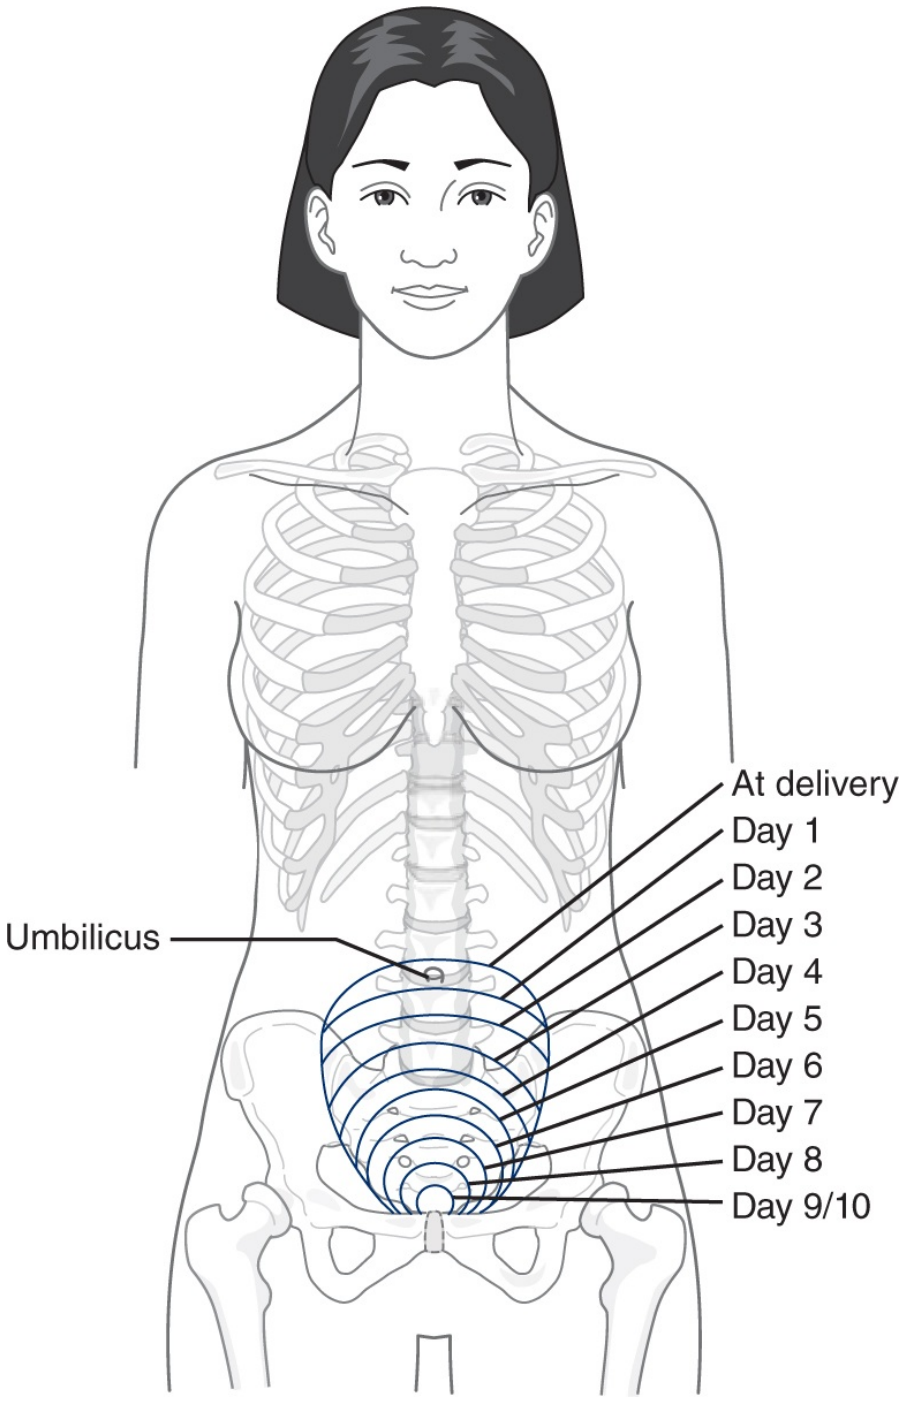

Figure 32-3 Postpartum involution of the uterus. The fundal height descends toward the pelvis at a rate of approximately 1 centimeter per day.

Postpartum Hemostasis

Following placental separation and expulsion from the uterus, a series of events must occur to ensure maternal hemostasis at the placental attachment site. This series of events begins prior to placental separation, with oxytocin-induced contractions of the myometrium that cause a permanent and progressive shortening of the muscle fibers. In addition to promoting the separation of the placenta from the uterine wall, this shortening and retraction of muscle fibers

compresses the maternal arteries that served as the vascular supply to the placenta.[31] As the myometrium contracts, the uterine walls press against each other, which may also promote hemostasis.

The mechanical compression caused by myometrial contractions is the primary mechanism of hemostasis in the immediate postpartum period. In addition, a clotting response is initiated at the time of placental expulsion that further contributes to hemostasis at the placental attachment site. Uterine atony during the first hour following delivery can lead to massive maternal hemorrhage, especially if the contractions are inadequate.

During pregnancy, changes in the coagulation and fibrolytic systems promote coagulation via an increase in platelet activity, a decrease in fibrinolysis, and an increase in coagulation factors. This “hyper-coagulable” state encourages and supports adequate coagulation at the placental attachment site and protects against hemorrhage following birth. In brief, during pregnancy (and particularly in the third trimester) the woman experiences an increase in a number of clotting factors (I, II, VII, VIII, IX, and XII), a decrease in protein S levels, and a progressive fall in the activity of activated protein C.[32] Postpartum, these clotting factors promote coagulation of the sheared maternal vessels at the placental attachment site. However, while the clotting factors protect a woman from hemorrhage, they also predispose her to thromboembolic events.[33,34] The relative proportions of coagulation factors appear to return to their nonpregnant state by 3 weeks postpartum, but certain clotting cofactor levels, such as protein S levels, may not return to normal levels until 8 weeks postpartum or later.[33,35]

Uterine Involution

Uterine involution is the process of uterine contraction, myometrial cell shrinkage, and reestablishment of the endometrium. The uterus involutes by approximately 50% in the first 24 to 48 hours postpartum and then gradually diminishes to the nonpregnant size over the next 6 to 8 weeks.[29] This process takes longer in multiparous women than in primiparous women.[36]

During involution, the uterus loses mass secondary to myometrial cell autolysis. The result is a marked decrease in the size—rather than the number—of myometrial cells. Approximately 90% of the excess cellular protein is broken down by proteolytic enzymes that are released by myometrial cells, endothelial cells of uterine blood vessels, and macrophages.

The uterine decidua is divided into multiple layers (strata) during pregnancy. Postpartum, the placenta separates at the spongy portion of the layer known as the decidua basalis, most of which is sloughed off with the placenta or in the early postpartum period. In the second and third postpartum days, the remaining decidua becomes differentiated into two layers, identified as the superficial and basal layers. The superficial layer is formed through leukocyte invasion and protects the desquamated endometrium from infection. This layer becomes necrotic and is sloughed off. In contrast, the basal layer remains intact and gives rise to the new endometrium through proliferation of the remaining glandular and stromal tissue. By 1 week postpartum, the endometrial surface has become epithelized; by 2 to 3 weeks postpartum, the endometrium has regenerated and resembles a nonpregnant endometrium, excluding the placental implantation site. The remaining thrombosed vessels at the placental implantation site take approximately 6 weeks to heal through an “exfoliation” process of sloughing infarcted and necrotic tissue,

followed by a process of endometrial remodeling.

Lochia

The postpartum vaginal discharge that begins immediately at birth and continues for approximately 4 to 8 weeks is termed lochia. The mean total duration of lochia is 33 days.[37–39] Lochia is further described as lochia rubra, lochia serosa, and lochia alba based on its changing color.[39] This color results from the changing composition of the tissue that is sloughed and expelled in the postpartum endometrial restoration process.

Initially, the lochia consists primarily of blood; as a result, *lochia rubra* is red or brownish red in color. As the uterine bleeding decreases at approximately 3 to 5 days postpartum, leukocyte infiltration occurs and the placental implantation site undergoes exfoliation. At this point, the discharge contains some blood but primarily wound exudate and leukocytes; therefore, *lochia serosa* is a pinkish brown color. The median duration of lochia serosa is 22 days.[37,38] Some women will experience a transient increase in bleeding 7 to 14 days postpartum secondary to sloughing of the placental eschar (scab) at the placental site. Toward the end of the uterine involution process, the endometrium has been primarily restored. *Lochia alba* is composed predominantly of leukocytes and some decidual cells and is white or yellowish white in color.

Cervical and Vaginal Involution

During labor, the maternal cervix undergoes remodeling to become soft and dilated; it also shortens so that it is not palpable as distinct from the lower uterine segment. The first two stages of remodeling are described in more detail in the *Anatomy and Physiology During Labor and Birth* chapter. After the birth of the newborn, the cervix begins to reconstitute. At this point, it may appear edematous and have sustained lacerations. Internally, the extracellular matrix is repaired and the epithelial barrier restored during this process.[40] By the end of the first week postpartum, the endocervical canal has reappeared and the os is only approximately 1 centimeter dilated. The external cervical os usually does not return to its previous nonpregnant form with the dimple shape characteristic of most cervices of nulliparous women, but rather takes the form of a slit (**Figure 32-4**). The cervical endothelium also undergoes remodeling during the postpartum period, which has been associated with a high incidence of spontaneous regression of high-grade cervical intraepithelial lesions.[41]

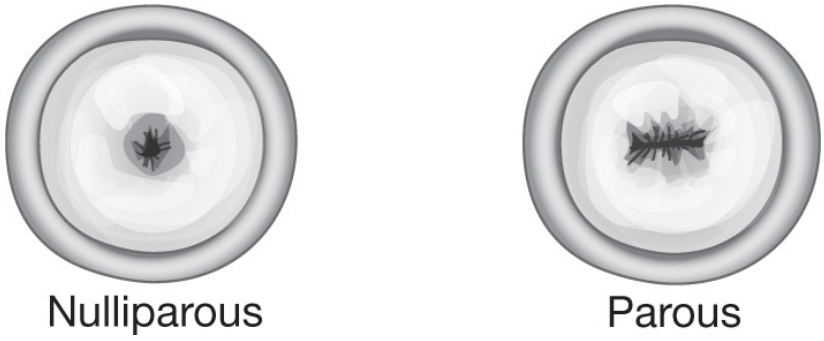

Figure 32-4 Postpartum anatomic changes in the cervix.

The vagina is initially edematous and bruised after a vaginal birth and has lost its prepregnant tone and rugae. The vaginal rugae return at approximately 3 to 4 weeks postpartum, but the prepregnant vaginal tone may never be completely restored. The vaginal epithelium is usually healed by 6 to 10 weeks postpartum. Following a woman's first vaginal birth, the hymeneal ring is replaced by hymeneal tags and the vaginal opening becomes visible rather than closed by the labia minora.

Wound Healing

Some women experience perineal lacerations during the process of vaginal birth, or from the use of forceps, vacuum, or cutting of an episiotomy. Identification, categorization, and repair of perineal and vaginal lacerations are described in the appendices of the *Second Stage of Labor and Birth* chapter. The wound healing process is divided into three phases: hemostasis and inflammation, granulation and proliferation, and remodeling.[42]

Hemostasis and Inflammation

The hemostatic process begins immediately at the time of injury and continues for a few days. First, platelets adhere to damaged tissue and combine together to form a platelet plug. Fibrinogen is attracted to this platelet plug, where it is subsequently cleaved into fibrin via the action of thrombin. Fibrin is an elastic, insoluble protein that forms an interlacing fibrous network that stabilizes the area of blood vessel injury. Platelets also release growth factors that call fibroblasts to migrate to the area, as well as cytokines that mediate the initial inflammatory response.

The inflammatory response begins within the first 6 to 8 hours following the perineal injury.[42] Polymorphonuclear neutrophils (PMNs) from blood vessels in and surrounding the injured area migrate to the area of injury. These white blood cells work to rid the area of bacteria, damaged cells, and cell debris. The PMNs also assist in recruiting monocytes to the area, which then differentiate into macrophages and cleanse the area of foreign cells as well as damaged and dead cells via the process of phagocytosis. Unlike the PMNs, which are part of the initial inflammatory response and are short-lived, macrophages can live for months. After approximately 3 or 4 days, in addition to their work in ridding the area of debris and foreign and dead cells, the macrophages begin to release key growth factors that trigger the growth of new tissue in the area. During this phase, the woman may experience swelling, burning, or pruritus in the area in which the laceration occured.

Granulation and Proliferation

Approximately 5 to 7 days after injury, the fibroblasts that were recruited in the initial inflammatory response migrate to the area of the wound and begin to lay down the extracellular matrix and collagenous tissue in the area that serve as the “framework” or scaffold for the rebuilding of the new tissue. Revascularization (angiogenesis) is essential to feed the new (granulation) tissue with nutrients and oxygen. New vessels arise as branches from intact vessels in the area. Regrowth of the epithelial layer occurs as epithelial cells migrate to this layer from the edges of the injured area or from adjacent tissues. This process can take up to 4 to 5 weeks.

As the granulation tissue grows to fill the wound, the area will take on a red or pebbled pink appearance, particularly if the tissue is healing via secondary intention (not approximated by sutures). This new tissue is highly vascular and friable. As part of health education, the woman should be advised to keep the area clean and to blot the area dry after urinating/defecating or

after washing. Blotting is preferred instead of wiping, to avoid damaging this new tissue. Women who have sutures in place should be made aware that, depending on the suturing material, it may take 6 weeks or longer for the sutures to be fully absorbed.

Remodeling

During the last phase of wound healing, the collagen tissue undergoes remodeling to become similar to the prebirth tissue; this phase can last for years. Many of the new blood vessels created during the proliferative stage of wound healing begin to regress. Wound contracture occurs secondary to the action of specialized contractile fibroblasts known as myofibroblasts. The collagen scar tissue, and particularly the initial scar tissue that has not undergone remodeling, will feel thicker and less distensible—a change that may contribute to postpartum dyspareunia. As the healing process continues, some women describe the scar tissue as transitioning from feeling painful to feeling numb. With time, the tissue is likely to regain most of its elasticity and sensation. The scar tissue is not as strong or elastic as normal tissue, however, and there is an increased risk of lacerations along the scar tissue with subsequent births.

Postpartum Physiology in Nonreproductive Organs

Pregnancy results in anatomic and/or physiologic changes in every organ system of the body, all of which are altered again during the puerperium (**Table 32-2**).[43-53] These physiologic changes may disappear over time depending on the organ involved and the underlying health of the individual woman. Because of their importance and profound changes, the postpartum changes that affect the cardiovascular and endocrine systems are described here in detail.

Table 32-2 Postpartum Maternal Physiologic Adaptations

Postpartum Change	Timing of Return to Nonpregnant Status	Clinical Notes
Cardiovascular		
Auto-transfusion of 10% to 15% of blood volume secondary to removal of the placenta and shifting of extracellular fluid into the intravascular system. Stroke volume and cardiac output increase by 80%.	Immediate	Women with hypertension, preeclampsia, or cardiac disease have an increased risk for pulmonary edema or cardiac failure in the first 24–48 hours postpartum.
Cardiac output is increased secondary to the increased flow of blood back to the heart from the loss of the uteroplacental circulation, decreased pressure from the pregnant uterus, and mobilization of extracellular fluid.	Cardiac output increases during the first 48 hours after birth, then slowly returns to normal by 6–12 weeks postpartum.	Women with some types of cardiac disease can be at risk during the postpartum period for cardiac failure, pulmonary edema, and other cardiac abnormalities.
Plasma volume slowly returns to nonpregnant values.	2 weeks postpartum	Women have a natural diuresis and diaphoresis in the initial postpartum period.
Hematologic		
Impaired fibrinolysis normalizes.	24–48 hours	
WBC levels normalize.	6 days	WBCs are elevated in labor and gradually return to normal in the puerperium.
Coagulation factors normalize.	4–6 weeks	An increased risk for thromboembolic events is present for the first several weeks postpartum.
Platelet function normalizes.	12 weeks	
Respiratory		
Removal of the weight of the gravid uterus at birth relieves intra-abdominal pressure and allows for elevation of the diaphragm, so that normal excursion of the diaphragm is reestablished.	Immediate	The dyspnea related to pregnancy usually resolves rapidly after birth. Therefore, complaints of shortness of breath or chest pain in the postpartum period should be evaluated immediately, especially because of the increased risk of thromboembolic events in the postpartum period.
Decrease in tidal volume back to normal.	Immediate	
Loss of placental progesterone production, a mediator of many		

respiratory changes of pregnancy, leads to a rapid return of normal nonpregnant respiratory parameters.		
Return of normal RV and ERV that were decreased during pregnancy.	RV returns immediately; ERV takes several months to return to nonpregnant values.	
Renal		
Gradual return to nonpregnant values of GFR, renal plasma flow, plasma creatinine, BUN, and creatinine clearance, all of which were altered during pregnancy.	2–3 months postpartum	Alterations may reflect changes of pregnancy that have not returned to nonpregnant levels.
Mild proteinuria may develop in the first few postpartum days.	3–5 days	New-onset proteinuria may be related to normal postpartum changes. However, evaluation for preeclampsia should occur if new-onset proteinuria is noted in the first 2–3 weeks postpartum.
Natriuresis (sodium excretion) and diuresis (increased urine production) lead to a decrease in blood volume, causing it to return to nonpregnant levels.	3 weeks or less	Oxytocin promotes reabsorption of water. The decrease in oxytocin contributes to postpartum diuresis. Urine production in postpartum days 2–5 can reach 3000 mL. In addition to increased urine production, many women will experience episodes of diaphoresis in the first postpartum week.
Gradual return of bladder tone and normal size and function of the bladder, ureters, and renal pelvis, all of which were dilated during pregnancy.	6–8 weeks, although it may take longer	Changes of pregnancy and trauma, including interventions, during the birth of an infant can lead to an increased risk of urinary tract infections and urinary retention during the postpartum period.
Hepatic		
Liver function indices (AST, ALT, LDH) that increased during labor return to normal.	3 weeks or less	Interpretation of liver function tests drawn in the postpartum period must reflect the knowledge that alterations from pregnancy and/or labor may not have returned to nonpregnant levels.
Alkaline phosphate, which increased during pregnancy, returns to normal.	6 weeks	
Gastrointestinal		
Gastric tone and motility remain decreased for 2–3 days postpartum.	Bowel movements resume 2–3 days postpartum; normal GI function and bowel patterns return in 1–2 weeks postpartum	Decreased GI motility in the postpartum period can lead to abdominal distension, constipation, and, in severe cases, ileus.
Musculoskeletal		
Ligaments and muscles are lax, so the abdominal wall remains soft and flaccid in the immediate postpartum. Separation of the rectus muscle (diastasis recti abdominis) may be present.	Variable	The recovery of abdominal muscular tone and resolution of diastasis recti abdominis are somewhat related to activity/exercise.

Musculoskeletal		
Muscles and associated tissues that were stretched during childbirth gradually regain tone.	Variable, but can take months to years	Stretching and injury of the pelvic and perineal musculature and associated structures increase the risk of urinary and anal incontinence as well as pelvic organ prolapse. Prevention of these complications includes avoidance of episiotomy and performance of postpartum pelvic exercises.
Integument (Skin and Hair)		
Hyperpigmentation (including linea nigra and melasma), striae gravidarum (stretch marks), varicosities, and other skin changes of pregnancy fade or regress.	6 months or less	Many skin changes do not disappear completely. Striae commonly progress from red to silvery white in color in approximately 3 months.
With return of estrogen levels to nonpregnant levels, hair growth slows and follicles enter into a hair-shedding phase, which results in a period of alopecia or postpartum telogen effluvium.	Normal hair growth is reestablished by 4–6 months postpartum for most women	Reports of hair loss in women in the postpartum period are common, and the provider can offer reassurance. Women with excessive hair loss leading to bald patches or with hair loss lasting longer than 6 months should be evaluated for thyroid dysfunction or nutritional deviations.
Metabolism		
Demand for nutrients and hormone levels drop abruptly. Maternal metabolism of nutrients begins to return to normal. Maternal insulin resistance seen during pregnancy begins to resolve shortly after removal of the placenta.	Fasting glucose plasma levels and plasma free fatty acid levels return to prepregnant levels in the first 3–5 days for women with normal glucose metabolism in pregnancy; triglyceride levels normalize within 2–3 weeks	Insulin resistance resolves nearly immediately following birth, which may require medication adjustment for women with Class A2, GDM. Maternal glucose values should be back to normal by the 6-week postpartum visit. Women with GDM should be screened for continued glucose intolerance at 6–12 weeks postpartum.
The increase in intestinal calcium absorption seen during pregnancy resolves to nonpregnant levels of calcium absorption.	6 weeks in nonlactating women	In women who are lactating, increased calcium needs for breast milk are supported by increased reabsorption of calcium from the skeleton. This process is associated with a reversible decrease in maternal bone density.
Endocrine		
The thyroid-binding globulin level decreases, which leads to a drop in T_3 and T_4.	First 3–4 days	After giving birth, women are at increased risk for Graves' disease, postpartum thyroiditis, and thyroid storm. Diagnosis can be complicated.
Endocrine		
FSH and LH levels are low	2 weeks Nonpregnant values return by 4–6 weeks in nonlactating women	Ovulation is highly unlikely in the first 2 weeks postpartum. Return of FSH and LH levels to normal is related to lactation status; ovulation occurs earlier among nonbreastfeeding women than those who lactate.
Prolactin and oxytocin	Fall to normal nonpregnant values in 7–14 days if not lactating	See the *Breastfeeding and the Mother–Newborn Dyad* chapter for a review of lactogenesis II. Pituitary disorders can cause an alteration in prolactin levels that interfere with lactogenesis.

Abbreviations: ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; ERV, expiratory reserve volume; FSH, follicle-stimulating hormone; GDM, gestational diabetes; GFR, glomerular filtration rate; GI, gastrointestinal; LDH, lactic dehydrogenase; LH, luteinizing hormone; RV, residual volume; WBC, white blood cell.

Cardiovascular and Hematologic Changes

A series of significant and rapid cardiovascular changes occur in the immediate postpartum period—namely, loss of blood, auto-transfusion of 10% to 15% of blood volume secondary to removal of the low-pressure fetal–placental unit,[47] and mobilization of extracellular fluid back into the maternal circulation. These dramatic fluid shifts make the postpartum period a period of maternal cardiovascular instability and a time of increased risk for adverse outcomes, including pulmonary edema, cardiac failure, and death, in women with preexisting cardiac disease, hypertension, or preeclampsia.

In the first 10 to 15 minutes after the newborn's birth, maternal stroke volume and cardiac output are increased approximately 80% above pregnancy levels.[52] This effect is hypothesized to be due to increased cardiac preload that results from auto-transfusion of utero-placental blood back into maternal systemic circulation and improved venous return with decompression of the vena cava secondary to removal of mechanical pressure from the gravid uterus. In the first postpartum hour, stroke volume and cardiac output remain elevated and heart rate decreases, but mean arterial blood pressure is unchanged.[52]

Mobilization of extracellular fluid back into circulation in the first few postpartum days also contributes to increased maternal blood volume. This acute increase in blood volume helps compensate for the normal blood loss of parturition. Following the sudden increase in cardiac output immediately after birth, the woman's blood volume declines to prepregnant levels over a period of approximately 2 weeks. Normal return of cardiovascular function depends in part on a physiologic diuresis in the first week postpartum. Without normal excretion of the extracellular fluid into the intravascular system, there is an increased risk of pulmonary edema, particularly among women with cardiac disease or preeclampsia.

The increase in stroke volume first during pregnancy and then during the postpartum period leads to a temporary increase in the size of the left atrium of the heart.[48] This physiologic ventricular hypertrophy resolves more slowly than the increase in stroke volume and cardiac output. Left ventricular size does not return to normal until approximately 6 months postpartum.[48]

The blood loss that occurs during birth causes a marked decrease in the woman's red blood cell (RBC) volume. In addition, a period of hemodilution arises in the first postpartum week due to the increase in plasma volume that occurs as interstitial fluid is mobilized. The loss of RBCs combined with this hemodilution leads to a decrease in hemoglobin and hematocrit in the first postpartum week. A woman's hemoglobin and hematocrit gradually return over a 4- to 6-week period to their prepregnant values as plasma volumes and RBC production return to normal.

Endocrine Changes

An abrupt drop in the blood levels of multiple hormones—including human placental lactogen (hPL), human chorionic gonadotropin (hCG), estrogen, and progesterone—occurs when the placenta is expelled. This event sets in motion a series of endocrine alterations, including changes in glucose and lipid metabolism and the initiation of lactogenesis II.

With decreasing levels of circulating estrogen, the thyroid-binding globulin level (which was elevated in pregnancy) also drops. This change, in turn, leads to less production of triiodothyronine (T_3) and thyroxine (T_4) and a gradual return to nonpregnant thyroid function. Nevertheless, thyroid dysfunction is more common in the postpartum period than in other times during a woman's life. The incidence of thyroid dysfunction is 7% to 10% in the postpartum period versus 3% to 4% in nonpregnant women.

Postpartum thyroid dysfunction, including postpartum thyroiditis, is often transient. Postpartum thyroiditis—a thyroid disorder that manifests during the first postpartum year—is thought to be an autoimmune disorder that is unmasked in the postpartum period due to the rebound in immunologic function that follows pregnancy.[49] In approximately 23% of women, thyroid dysfunction will become permanent.[50]

The marked changes in the maternal hormonal milieu in the postpartum period are postulated to be the cause of postpartum mood disorders, including postpartum depression. Studies that have evaluated the link between hormonal changes and the development of depression have yielded contradictory results and, in general, have not found a consistent link between hormone levels and postpartum depression.[51] Significant methodological difficulties arise when trying to identify a causal link between any given biologic factor and the development of mood disorders, particularly at a time when all physiologic and psychosocial systems experience significant changes. However, lack of evidence does not necessarily mean that no such link exists. Currently, hormone levels cannot be used to effectively predict the development of postpartum mood disorders or to determine the need for treatment.

Resumption of Pituitary Function and of Menstruation and Ovulation

Throughout pregnancy, the hypothalamic–pituitary–ovarian (HPO) axis is suppressed and, as a result, production of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) is also suppressed. Following birth, FSH and LH levels remain low for the first 2 postpartum weeks, but then rise gradually. Ovarian production of estrogen and progesterone, therefore, also remains low during the first few postpartum weeks.

Pituitary function returns to nonpregnant levels by 4 to 6 weeks postpartum. However, return of nonpregnant levels and patterns of gonadotropin-releasing hormone (GnRH), FSH, and LH secretion are related directly to lactation status. In breastfeeding women, the return of ovulation and menstruation varies and reflects both the duration and frequency of breastfeeding. Elevated levels of prolactin, along with other endocrine alterations related to frequent and regular infant suckling, disrupt the pulsatile release of GnRH, which in turn suppresses the LH surge. This cascade of events culminates in the suppression of ovulation. Even once ovulation is resumed, women who are breastfeeding are more likely to experience

nonfertile ovulation. This breastfeeding-related suppression of ovulation and menstruation is referred to as “lactational amenorrhea.”

In nonlactating women, the return of ovulation occurs sometime between postpartum days 45 and 94.[53] As many as 70% of these ovulations may be fertile, and in 20% to 70% of women, ovulation precedes the first menses.[53] Therefore, appropriate contraceptive counseling is essential for postpartum women since many—particularly those who are not breastfeeding—may ovulate and be fertile prior to their first postpartum visit. For women who desire to defer another pregnancy for a period of time, timely initiation of the woman’s chosen method of contraception is an important management intervention.

Weight Loss in the Postpartum Period

Weight loss following pregnancy is a common concern for women. Aside from the immediate weight loss that occurs directly related to the birth of the baby, expulsion of the placenta, and loss of fluid in the first postpartum week, the physiology of weight loss (which is beyond the scope of this chapter) does not appear to differ in the postpartum period from the physiology of weight loss at other times in a woman’s life. The rate and amount of weight loss in the postpartum period seem to be determined by the same factors that determine weight loss at any point in a woman’s life, including existing weight/body mass index (BMI), diet, age, and activity level.[54] Furthermore, studies indicate that pregnancy weight retention is not a significant determinant of excessive weight. A study of 7000 women who were followed from the beginning of one pregnancy to the beginning of the next pregnancy found that the average increase in weight between the first pregnancy and the next was 3.4 kg.[55]

In recognition that humans tend to gain weight as they get older, additional studies that controlled for age found an increase of only 0.3 to 0.5 kg between pregnancies.[55] These findings suggest that interventions to reduce rates of maternal obesity should focus not only on the loss of weight gained in pregnancy, but also on primary prevention of obesity and weight management at a preconceptional visit.

Conclusion

The postpartum period is a time of remarkable and rapid physiologic adjustment. Knowledge of postpartum physiology is necessary to determine the difference between normal and abnormal progression during this period. Moreover, although the vast majority of women in the postpartum period have a normal course of recovery, it is important to teach all women about signs of danger and worrisome symptoms in the postpartum period. Finally, despite a relatively rapid change from the physiology of pregnancy to a nonpregnant physiologic state, it is important to remind the woman that it is quite normal for her not to feel completely back to "herself" during the weeks and even months following the birth of a newborn. The postpartum period is a profound role transition and life-changing event that cannot be described via a review of anatomic and physiologic changes.

Postpartum Care

Introduction

The end of pregnancy initiates physiologic changes, as many organ systems return to their nonpregnant states. The uterus involutes, cardiac output and blood volume decrease, and estrogen and progesterone levels fall. Lactogenesis II begins and may continue for years in women who chose to breastfeed. Yet the postpartum period is so much more than just these physical changes—birth transforms the social and emotional context for the woman and her family.

Definition of the Postpartum Period

Pregnancy comes to a definitive end with the delivery of the placenta and membranes. At this time, the woman begins the physiologic transition to the nonpregnant state. Traditionally the postpartum period, or puerperium, has been defined as lasting 6 weeks: By 6 weeks after giving birth, most women have completed the last of the physiologic transitions, which include uterine involution, cessation of lochia, and establishing lactation. This is a somewhat arbitrary—and an arguably short—time frame for the transition to parenting. An alternative definition of the postpartum period is the "fourth trimester," which suggests a transition that lasts approximately 3 months.

While "recovery" implies healing from illness or trauma, the postpartum transition, as a normative life experience, is more than that. With the arrival of the newborn, family members assume new roles both within the family and in the community. For many families, employment status may change for either parent. As definitions of "family" have expanded in recent decades, recognition that there are considerable variations in a family's adjustment after childbirth has become more widespread. Despite the significance of these changes, women and families may receive less attention and support during the postpartum period than they did during pregnancy and the intrapartum period. As a consequence, the postpartum period is a time of both opportunity and challenges to health.

Postpartum Care in the United States

Standard postpartum care in the United States today includes the traditional model of an office visit with the prenatal care provider at 4 to 6 weeks postpartum, although women who were followed prenatally in a group setting such as the CenteringPregnancy usually have a group reunion at 1 to 2 months. Thus, after hospital discharge, many women do not have contact with their healthcare provider until the 6-week postpartum office visit, and a significant number of women do not attend this visit. It is unclear why this specific time frame was selected, and in some centers, it has been replaced by an earlier examination at 2 to 3 weeks. An additional office visit at 1 to 2 weeks postpartum has been proposed to bridge the gap in care from discharge until 6 weeks, and to support breastfeeding, contraception, and the psychosocial transition postpartum. The financial pressures of clinical practice deter many providers from providing this extra visit, however, as there often is no additional reimbursement for it.

In developed countries, there is a wide variation in the amount of financial support provided to women after childbirth. In the United States, unpaid parental leave is guaranteed for 12

weeks under the Family and Medical Leave Act, but only approximately 56% of women are eligible for this job protection.[1] For many families, taking time off to care for the woman or infant in the postpartum period places the family at significant financial risk. This economic challenge in the United States stands in contrast to policies in most other developed countries, where paid maternal leave extends from 14 weeks (e.g., Singapore and Switzerland) to longer than a year (e.g., Japan and Finland). In some countries, there is a similar range of paid paternal leave.[2]

Cultural Perspectives of the Postpartum Period

The first essential perspective for provision of effective postpartum care is understanding the woman in her social and cultural context so that the care provided is culturally sensitive. Throughout history, in all parts of the world, and across cultures, the postpartum period has been acknowledged as a special or vulnerable time during which women follow distinct rituals. For example, Mexican–American immigrant families may practice the *cuarentena*, or 40 days of postpartum recovery.[3] During this time, the woman's body is considered open and vulnerable to illness. Practices to protect the woman include sexual abstinence, wrapping the abdomen in tight garments (*fajas*), avoiding strong foods and cold substances, and remaining at home as much as possible.

In many parts of Asia, the new mother remains at home and rests for 30 to 40 days after giving birth—a practice often referred to as "doing the month."[4] This period of prolonged rest protects the woman from exposure to illness and conserves warmth that she needs for caring for her newborn. To maintain warmth, the woman may eat special foods, avoid showering, and stay in bed. Often a female family member will stay with her for the first few months to do the cleaning and cooking so that the new mother can rest. Similarly, Chinese women may follow the practice of *zuo yuezi*, or "sitting the month."[5,6] During the first month postpartum, they are cared for by their mothers, mothers-in-law, or grandmothers; avoid cold foods; and keep themselves warm by wearing long clothing and staying indoors. In addition to its protective qualities, sitting the month is seen as a way to show respect to elders' beliefs and to traditions that have been observed for millennia.[6] Vietnamese women also view the postpartum state as a cold state (*duong*) and, therefore, protect themselves through warmth (*am*). Cultural practices include warm water for bathing and stimulating lactation, staying indoors, and consuming foods that have warm qualities, such as meat, eggs, ginger, and wine.[7] The postpartum cultural practices in southeast Turkey are surprisingly similar to those of both the Asian and Latin cultures. These practices include avoiding cold foods, and remaining at home on reduced activity for 40 days.[8] A common characteristic of all these practices is the provision of additional social support to the woman after childbirth.

When a woman is geographically distant from her extended family, it may be difficult to maintain cultural practices.[9] Knowledge about other cultures and practices is a necessary beginning for midwives, but it is also important to incorporate this knowledge into clinical practice with curiosity and humility, so that women and families are treated as *they* wish to be treated. To accomplish this balancing act requires an ongoing process of clinical inquiry and communication with women to provide care that is culturally congruent—that is, care that fits with the family's values and meanings.[10,11] Questions that can help the midwife conduct a cultural assessment are listed in **Table 33-1**. Resources for providing culturally congruent midwifery care can be found at the end of this chapter.

Table 33-1	**Postpartum Cultural Assessment**
Consider the following questions when caring for women and families postpartum: Is the postpartum period viewed as a normal physiologic process, a wellness experience, a time of vulnerability	

and risk, or a state of illness? What does the postpartum experience mean to the woman?

Is the postpartum period a time for privacy or socialization?

What kinds of support are the new family given during the postpartum period, and who gives that support?

Are there culturally expected practices during the postpartum period regarding diet, nutrition, treatments (including pharmacologic therapies), and activity?

What maternal precautions or restrictions are necessary during the postpartum period?

How is postpartum pain managed?

What are the patterns regarding care of the infant and relationships within the nuclear and extended families? Are there expected patterns for feeding and caring for the infant?

Beyond Gender

Parenting is a gendered, socially constructed experience. Lesbian, gay, bisexual, queer (LGBQ) and transgender and gender nonconforming (TGNC) parents may have different psychosocial experiences of childbirth, and little is known about their postpartum experiences. These families may experience difficulty interacting with the healthcare system due to heterocentric practices in language use and history forms, discriminatory practices, and lack of support from the extended family.[12] Assumptions about gender-based parenting roles may not be valid. For example, either female parent may choose to breastfeed in lesbian couples. Transgender men may experience the physical aspects of childbirth differently than do other parents.[13] Due to the additional stresses facing these families, a supportive environment, healthcare team, and social network are important for birth and postpartum care.[14] The midwife should use an approach of cultural humility and inquiry in caring for trans parents, and use language that supports their preferred pronoun and gender identity. General healthcare issues germane for LGBT and TGNC individuals is briefly reviewed in the *Midwifery: Clients, Context, and Care* chapter.

The First Hour Postpartum: The Fourth Stage of Labor

The term *fourth stage of labor* refers to the first postpartum hour following placental expulsion. Immediately following the expulsion of the placenta, a number of maternal changes occur as the physical and emotional stresses of labor and birth resolve and postpartum recovery and bonding begin. Close observation and frequent assessment as described in **Appendix 33A** are needed during the fourth stage of labor, as this is a time of both physical vulnerability to emergent complications and heightened sensitivity as the woman and family are introduced to the newborn. This section presents a brief overview of maternal–infant behaviors during the initial first postpartum hours and evidence-based practices that support attachment and the formation of the family.

Maternal–Infant Bonding and Attachment

The theory that there is a biologically determined critical period immediately after birth during which maternal–newborn bonding takes place was first proposed by Klaus and Kennell in the 1970s.[15] These researchers found that skin-to-skin contact between the woman and her newborn in the first hour after birth resulted in more attachment behavior by a woman toward her infant up to a month after birth. This seminal work by Klaus and Kennell set the stage for the plethora of subsequent research that has profoundly influenced the care of women, newborns, and families in the postpartum period. Emotional attachment between parents and their newborn has lifelong implications.

During the fourth stage of labor, the woman experiences profound physical and psychological changes as she recovers from the act of giving birth in the setting of an intense hormonal milieu and first meets the newborn. Partners, grandparents, siblings, and other family members or support persons present at a birth also experience heightened awareness and possible psychological vulnerability. Factors such as a traumatic birth, previous life traumas, or newborn illness can all influence an individual's response to childbirth, attachment to the newborn, and development of identity and role as a mother or primary caretaker.

Definitions of parent–infant attachment have historically included concepts such as bonding, love, attachment, or an instinctual connection. The initial development of attachment between parents and a newborn takes many forms; the response of one parent may differ from the other. More importantly, the process is bidirectional and includes a great deal of interactive and reciprocal behaviors. The infant's primary behavior is seeking physical proximity. The mother's (or other primary caregiver's) behavior demonstrates responsiveness to the newborn's cues. For example, animal and human studies of bonding in the first postpartum hour have found that healthy newborn infants undergo a predictable series of behaviors immediately after birth, including crawling toward the mother's breast, rooting and suckling, and looking at the mother's face.[16] It is theorized that this behavior is stimulated by maternal odor and voice recognition.[17]

Goulet et al. used concept analysis methodology to examine the vast literature on attachment to develop a clearer understanding and definition of this process.[18] In their analysis, these authors identified three key attributes in the mutual relationship between parents and newborns.

- *Proximity*. Physical closeness allows interaction with multiple senses (e.g., hearing, touch, sight, and smell), facilitates a strong emotional connection, and creates an awareness of the infant's individuality and needs that are different from the parent's needs.
- *Reciprocity*. Parents and newborns interact in a responsive and adaptive manner. Parents become sensitive to the infant's cues and body language in their caregiving. The infant contributes to the interaction by reinforcing the parents' behaviors.
- *Commitment*. Feeling and acting responsibly to ensure the safety, growth, and development of the infant place the infant in a central position in the family and identify the parenting role as an important part of the adult's identity.[18]

An important caveat to bonding theory is that much of this work is based on animal studies, wherein immediate imprinting of the infant to the caregiver is biologically species specific. Superimposing the results of animal studies on human behavior may result in beliefs that have no scientific basis. In addition, the underlying premise that this sensitive period is necessary for the maternal–newborn relationship has been criticized. Attachment bonds form over time and involve a complex interplay of neural circuitry, hormones such as oxytocin, and interactive behavior.[19] Overemphasis on the first hour may be harmful in situations where it is missed, such as when the medical condition of the woman or the newborn requires physical separation of this dyad. Fortunately, there are countless opportunities to develop attachment, as demonstrated by parents who adopt children at a variety of ages. Continuing reciprocal responses, strengthening of the relationship, and changing roles are processes that occur throughout life, including during the postpartum period.

Caregiver interventions during the fourth stage of labor, including those related to medical, psychosocial, and environmental conditions, can either facilitate or interfere with these important processes. Despite incomplete knowledge about the exact neurobiology involved in maternal adaptation, a great deal of research has been conducted that has identified short-term and long-term effects of specific care practices such as skin-to-skin contact and early breastfeeding with newborn self-latching.

Early Continuous Skin-to-Skin Contact

Early skin-to-skin contact involves placing a naked newborn prone on the woman's abdomen or chest immediately or soon after birth. The infant is dried and the area of the infant's body that is not touching the mother's skin is covered with a blanket to assist in maintaining warmth. A cap may be applied to the dried head of the newborn to assist with temperature maintenance. The vital signs of the newborn and woman are monitored with the infant on the maternal chest. Other procedures are delayed for at least 1 hour or until after the first successful breastfeeding.

Continuous maternal–newborn contact and skin-to-skin touching have been found to improve maternal affectionate behavior, regulate the newborn's behavior, and increase the duration of breastfeeding.[20] Early contact also increases maternal sensitivity and the infant's self-regulation and irritability at 1 year after birth.[21] Moore et al. conducted a meta-analysis of 46 randomized controlled trials (RCTs) of early skin-to-skin contact (n = 3850 mother–infant

dyads) and found that skin-to-skin contact improved breastfeeding and breastfeeding duration at 1 to 4 months (relative risk [RR], 1.24; 95% confidence interval [CI], 1.07–1.43), although differences in study methodology and risks of bias casts some uncertainty on the strength of these findings.[21] Positive trends in improved summary scores for maternal affectionate love/touch, maternal attachment behavior, and shorter duration of infant crying were also noted in the group that experienced early skin-to-skin contact.[21]

In the first 2 hours after cesarean birth (**Figure 33-1**), neonates who were held in skin-to-skin contact with the father demonstrated less crying, became calmer, and were more drowsy than newborns left in a crib.[22]

Figure 33-1 Skin-to-skin contact and breastfeeding immediately after cesarean birth.

Courtesy of Tekoa L. King, CNM, MPH.

Oxytocin and cortisol are likely important mediators of early parent–infant interactions. Premature infants have better cardiorespiratory stability when exposed to skin-to-skin contact with their mothers.[21] Increased oxytocin levels have been demonstrated after skin-to-skin care in preterm infants[23] and after cesarean birth,[24] which suggests a physiologic mechanism for increased attachment and breastfeeding success in these contexts. Oxytocin levels in mothers and fathers have been shown to correlate with affectionate behaviors and touch at 6 months

postpartum.[25] Newborns who experience skin-to-skin care may attain heart rate stability and have lower salivary cortisol levels when compared to infants who do not share skin-to-skin contact with their mothers immediately after birth.[26] Given the strength of these findings, hospitals in the United States are increasingly instituting skin-to-skin contact immediately after birth for all women including in the operating room and recovery room following a cesarean birth.[27]

Newborn Self-Latching

When healthy term infants are placed in skin-to-skin contact during the first hours following birth, they frequently crawl and find the areola by themselves, and most will initiate suckling spontaneously.[16] Supporting newborn interaction with the parents may enhance the newborn's ability to self-regulate his or her behavior over the long term (i.e., improved sleep, social-interactive behavior, and language development).[16] The wide-ranging positive effects of unrestricted maternal–newborn contact reinforce the importance of protecting the family in the first hours after birth from unnecessary intervention.

Inclusion of Significant Others

Involvement of the woman's partner, newborn's father, or other support persons during the fourth stage of labor has been found to help the woman during the postpartum period,[28] increase the partner's emotional involvement with the neonate,[29] and increase the sense of security experienced by the partner.[30] Men and lesbian partners have expressed feeling helpless, useless, anxious, out of place, and vulnerable during birth; including family members in the experience is an important component of family-centered midwifery care.[31,32]

For all these reasons, it is important to assess and address the partner's needs during the fourth stage of labor to facilitate the transition to parenthood. Strategies include anticipatory guidance and explanations to the woman and her significant others. Support via midwifery presence and information has been found to enhance the birth experience of the partner.[33] Engaging partners in activities such as cutting the cord and skin-to-skin contact has been found to enhance their emotional involvement with the neonate.[29] Additional activities may include encouraging continued support for the woman during required genital tract repair, engaging in observation of the neonatal transition, and assisting with initial breastfeeding.

Early Breastfeeding

Evidence that breastfeeding improves health outcomes for women and their infants is overwhelming; this evidence is reviewed in detail in the *Breastfeeding and the Mother–Newborn Dyad* chapter. Initiation of breastfeeding in the first few hours after birth is recommended, as the infant is alert and awake during this time period. Activities during the fourth stage of labor that have been found to promote early breastfeeding include skin-to-skin contact between the newborn and mother following birth and maintaining this contact for the first few hours of life.[34] If the woman and her neonate must be separated for medical

indications, skin-to-skin contact in the intensive care nursery, early effective breast milk expression, and support from peers and staff can be implemented and are very important to the promotion of breastfeeding in neonatal units.[35]

Initial Postpartum Period

The first 72 hours after birth is labeled as the early puerperium period. The frequency with which the midwife evaluates the woman and newborn during this period will vary depending on the birth setting and individual circumstances. In most settings, the midwife assesses the woman at least once daily. Each visit includes a chart review; interval history, including physical, psychological, and emotional changes since the birth; physical examination; and observation of family interactions. Care of women during this period includes treatment of pain and common discomforts, immunizations as needed, and health education.

Health Record Review

The woman's prenatal record and record of labor and birth are reviewed prior to all postpartum examinations. A review of the infant's status is part of this pre-assessment because the newborn's health status may directly influence the management plan for the woman. A review of the health record includes assessment of the woman's vital signs, laboratory results, medication use, and comments from other caregivers. Previous orders and progress notes are reviewed as well. Medications that were temporarily stopped during the pregnancy or labor should be evaluated and a decision about restarting them made.

Time elapsed since birth, in hours or days, is ascertained to identify expected physical findings. When entering notes in the health record, it is important to indicate precise time information. For example, postpartum day 1 may denote that the woman is within 24 hours postpartum or between 24 and 48 hours postpartum. Since indicating postpartum days may generate confusion based on time of birth and calendar days, specifying how many *hours* have elapsed since the birth is preferred.

Interval History

The initial assessment of maternal physical well-being starts with eliciting information about nutrition, bladder and bowel function, activity level, and a description of pain or discomfort if present. Information about the infant feeding method, infant behavior, and sleep–wake cycles should be collected even if the midwife is not the primary provider for the newborn.

When a home visit is conducted, the midwife should arrange the visit to coincide with those times when the infant is likely to be awake if possible. This enables an evaluation of the parent–newborn interaction and the parents' skill and comfort in handling the newborn, which may indicate areas of learning needs. Examples of criteria for assessment of parent–newborn interactions are listed in **Table 33-2**.[36] Cultural factors need to be considered when evaluating the parent–newborn interactions.[37]

Table 33-2	Clinical Assessment of Parent's Interaction with Newborn
Uses gentle touch with newborn	
Positions infant for face-to-face interaction	
Directs gaze toward newborn when interacting	

Makes visual contact
Displays range of facial expressions
Verbalizes to newborn
Makes positive, affirming, loving comments to the newborn; avoids making disparaging comments
Modulates interaction in response to newborn's cues
Elicits verbalizations and behaviors from the newborn and responds contingently
Responds to newborn's distress

Modified with permission from Fowles ER, Horowitz JA. Clinical assessment of mothering during infancy. *J Obstet Gynecol Neonatal Nurs.* 2006;35(5):662-670.[36]

Physical Examination

The physical examination focuses on the physiologic changes that occur after birth, and includes assessment of the heart, lungs, breasts, abdomen, perineum and anus, and lower extremities. The postpartum examination procedure with expected findings is detailed in **Appendix 33B**.

Care of Women During the Early Postpartum Period

Specific components of care for women during the early puerperium can vary secondary to individual needs. In many hospital settings, routine or standing orders for the first postpartum days are used as a standard template for all women, but it is imperative that clinicians consider whether these orders are appropriate for the specific woman. The orders may need to be individualized—for example, by modifying pain management routines, discontinuing intravenous fluids, or requesting a referral to a lactation consultation. The midwife should be certain the topics outlined in **Table 33-3** are addressed if written orders are prepared, or that they are considered in the care of women delivering in out-of-hospital settings.

Table 33-3 Postpartum Orders and Plans

Topic	Details/Options
Hydration	Oral hydration preferred; should specify when to discontinue any intravenous hydration
Nutrition	Consider food allergies, cultural preferences, and diabetes
Activity level	Generally unrestricted; first time out of bed with assistance after epidural anesthesia, cesarean birth, or postpartum hemorrhage
Routine postpartum medications	RhoGAM if needed, vitamins and iron, stool softeners or laxatives, analgesics, immunizations, and sleep medications as needed
Preexisting medications	Continue or reinstate medications used prenatally, such as thyroid replacement and antidepressants, per the plan that was made prenatally. Consult with a physician colleague as indicated.
Perineal care	Ice packs, topical medications, peri-bottle
Management for inability to void	Peppermint oil essence in commode or toilet room, catheterization if necessary

Breast care	Purified lanolin cream or hydrogel for nipple soreness, breast pump for engorgement, binder/supportive bra for women who are not breastfeeding
Laboratory tests	Hemoglobin and hematocrit if symptoms of anemia or hypovolemia; Rh screen of the newborn if the woman is Rh negative
Immunizations	Rubella and varicella for nonimmune women; influenza if needed; HPV series can be resumed if discontinued during pregnancy; Tdap if not received during pregnancy
Contraception	Prescription for self-administered contraceptives; DMPA before discharge in selected clients
Discharge if in a hospital setting	Depends on family readiness and status of newborn
Follow-up	Postpartum clinics, home visits, 2 or 6 weeks in office

Abbreviations: DMPA, depot medroxyprogesterone acetate; HPV, human papillomavirus; Rh, Rhesus factor; RhoGAM, Rh immune globulin; Tdap, tetanus–diphtheria–acellular pertussis.

Rhesus Alloimmunization

Most women experience a small transfer of fetal blood into the maternal circulation (fetomaternal hemorrhage) during childbirth, primarily at the time of placental separation. If the fetal blood type is Rh D positive and the maternal blood type is Rh D negative, the fetal red blood cells that enter the maternal circulation are identified in maternal circulation as a foreign antigen. The fetal cells stimulate an immune response (alloimmunization) that produces immunoglobulin M (IgM) and immunoglobulin G (IgG) antibodies, which are directed against Rh D–positive red blood cells. In a subsequent pregnancy with a Rh D positive fetus, these antibodies can cross the placenta and bind to fetal red blood cells, causing hemolytic disease of the fetus and newborn. Approximately 17% of RH D–negative women who are not immunized will become alloimmunized.[38]

Anti-D immune globulin (RhoGAM) is a hyperimmune plasma derivative that binds fetal Rh D–positive cells and prevents the maternal production of anti-D antibodies.[39] Administration of anti-D immune globulin within 72 hours following birth reduces the risk of alloimmunization quite significantly (RR, 0.12; 95% CI, 0.07–0.23) and is recommended for all Rh D negative women who have a newborn with Rh D–positive blood who are not already sensitized.[40]

The newborn's blood type usually is tested on a small sample from the umbilical cord. If blood typing of the newborn's cord blood is not available, the benefits of Rh immune globulin administration to Rh D negative women outweigh the theoretical risks of unnecessary administration. Administration after 72 hours may be protective, and anti-D immune globulin should be given even up to 14 days after the birth, as no studies have been conducted that address the latest period for which the agent is effective. Because anti-D immune globulin is a blood product, it has theoretical risks of infection; however, current technologies screen the product for all known viruses, such as human immunodeficiency virus (HIV). Midwives should discuss its benefits and risks carefully with women, especially with women who object to the use of blood products.

The standard 300-mcg dose of anti-D immune globulin is sufficient to treat a fetal–maternal hemorrhage containing 15 mL of red blood cells or 30 mL of whole blood. While rare, it is important to know when the fetal–maternal hemorrhage exceeds this amount, because

additional anti-D immune globulin will be needed if the amount of hemorrhage is larger than 30 mL of whole blood. Therefore, a Rosette test is performed on the mother's blood to ascertain whether Rh-positive blood is detectable in the maternal blood. If the Rosette test is positive, a Kleihauer–Betke test is performed to determine the amount of fetal hemoglobin present. In some facilities, a Kleihauer–Betke test is the only test ordered because it entails the quantitative measurement of fetal red blood cells in maternal blood; the test results are used to determine if and how much additional Rh immune globulin should be administered.

Immunizations

The early postpartum period is an opportunity to provide women with protection against several infections. Women who received part of the human papillomavirus (HPV) vaccine series prior to becoming pregnant can complete that series postpartum. All women should be offered seasonal influenza vaccine regardless of their pregnancy status and should be offered this vaccine postpartum if the woman did not receive it during her pregnancy. Booster vaccination with tetanus–diphtheria–acellular pertussis (Tdap) should be administered to all pregnant women in the third trimester. This applies to all women, even if they received the vaccine prior to pregnancy or during a previous pregnancy.[41] The Tdap vaccine may be given in the postpartum period if it was not administered to the woman during pregnancy. Vaccination of all family members with a one-time dose of Tdap will also protect the infant from acquiring pertussis.[41]

Live-virus vaccines against rubella and varicella that are contraindicated during pregnancy should be offered to nonimmune women in the immediate postpartum period. The woman is not likely to be pregnant at this time, and no increased risk of congenital anomalies has been demonstrated if conception occurs within 1 to 3 months following vaccine administration. Nevertheless, it is recommended to delay conception at least 1 month after live-virus vaccine administration.

Common Discomforts in the Early Postpartum Period

Pain and fatigue are the most common discomforts experienced by most women the first several days after giving birth. Pain can be secondary to perineal lacerations or abdominal incisions, breast pain from engorgement, nipple pain related to infant suckling, uterine cramping, and hemorrhoids. Unmitigated pain can interfere with a woman's ability to care for her infant, delay recovery, and increase the risk for postpartum depression and for persistent pain.[42]

Treatment of Pain in the Early Postpartum Period

Both non-pharmacologic and pharmacologic treatments for pain can be used to manage breast or perineal pain. Individual medications usually are chosen based the severity of pain, mechanism of action, any known drug allergies, and compatibility with breastfeeding. Given the wide inter-individual variability in postpartum pain, an individualized stepwise approach

using a multimodal strategy is recommended.[43] Medications that are commonly prescribed to treat pain during the early puerperium are listed in **Table 33-4**.[43,44]

Table 33-4 Medications Commonly Prescribed to Treat Pain in the Early Postpartum Period

Drug: Generic (Brand)	Formulations	Indications and Dose	Clinical Considerations	Lactation
Acetaminophen (Tylenol)	325, 500 mg	*Mild to moderate pain* 500, 650, 1000 mg every 6 hours	Maximum: 4 g/day acetaminophen from all sources	Safe
Ibuprofen (Motrin, Advil)	200, 400, 600 mg	*Mild to moderate pain* 400 to 600 mg every 6 hours	Take with food Maximum: 3200 mg/day Avoid with hypertension All NSAIDs have a ceiling effect such that larger doses do not increase pain relief	Safe
Ketorolac (Toradol)	IM: 15, 30, 60 mg PO: 10 mg Should not be given PO as initial dose	*Short-term treatment for postoperative pain* 60 mg IM × 1 dose, then first PO can be 20 mg, followed by 10 mg PO every 4–6 hours	Reduces postoperative opiate use Maximum: 40 mg/day Do not use for women with renal impairment Do not shorten dosing interval to less than 4 hours	Safe
Acetaminophen (Tylenol)/ codeine No. 3	300/30 mg	*Moderate pain* Tylenol No. 3 every 4–6 hours	Take with food May cause excessive sedation in women and newborns who are rapid metabolizers	FDA advisory to avoid codeine in breastfeeding women if possible. If needed, use smallest effective dose for less than 4 days. Observe newborn for sedation, excessive sleepiness, and poor feeding.
Hydrocodone/ acetaminophen (Norco)	Hydrocodone/ acetaminophen combination as 5/325 mg, 7.5/325 mg, or 10/325 mg	*Moderate pain* 1–2 tablets every 4–6 hours	Maximum: 4 g/day acetaminophen from all sources	
Hydrocodone/ acetaminophen (Vicodin)	Hydrocodone/ acetaminophen combination as 5/300 mg	*Moderate pain* 1–2 tablets every 4–6 hours	Maximum: 4 g/day acetaminophen from all sources	
Vicodin ES	7.5/300 mg			

Abbreviations: IM, intramuscular; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, oral.

Based on American College of Obstetricians and Gynecologists. Practice advisory on codeine and tramadol in breastfeeding women. 2017. Available at: https://www.acog.org/Clinical-Guidance-and-Publications/Practice-Advisories/Practice-Advisory-on-Codeine-and-Tramadol-for-Breastfeeding-Women. Accessed December 28, 2017[43]; Fahey JO. Best practices in management of postpartum pain. *J Perinat Neonat Nurs*. 2017;31(2):126-136.[44]

Women who have experienced an uncomplicated vaginal birth may not require medication

stronger than ibuprofen (Advil) 600 mg taken orally every 6 hours as needed for either uterine cramping or perineal pain.[44] Nonsteroidal anti-inflammatory drugs (NSAIDs) appear to be more effective than acetaminophen or aspirin, probably because NSAIDs have both analgesic and antiinflammatory effects.[45] NSAIDs have a ceiling effect which means that increasing the dose beyond a certain point will increase the incidence of side effects but does not increase the analgesic effect. The ceiling dose for ibuprofen appears to be at approximately 400 mg per dose. NSAIDs transfer into breast milk in very small amounts are considered safe for lactating women.

Women who need stronger pain relief are usually treated with a hydrocodone–acetaminophen combination analgesic, but some cautions are warranted. The active metabolite of codeine and hydrocodone is morphine, which is lipophilic and crosses into breast milk. Individuals who have a genetic polymorphism that involves duplication of the enzyme CPY2D6 are ultra-rapid metabolizers of drugs such as codeine that are metabolized by CYP2D6. In 2006, the adverse effects of codeine use by persons who are ultra-metabolizers first became evident in a case report about a woman who took codeine for postpartum pain. Her ultra-rapid metabolism of the drug resulted in her infant receiving a large amount of morphine via breast milk; the infant died of morphine overdose.[46] Subsequently, the U.S. Food and Drug Administration (FDA) issued a warning about the use of codeine by breastfeeding women that noted the possibility of morphine toxicity in breastfeeding infants. In 2017, the FDA expanded the Drug Safety Communication to recommend that breastfeeding women and young children should not use codeine or tramadol.[47]

The frequency of CYP2D6 ultra-rapid metabolizers varies by ethnicity. Overall, in the United States, the prevalence is 4% to 5%.[48] Only 0.5% of persons with a Chinese ancestry have duplicates of this enzyme, but the prevalence is as high as 29% in persons from Ethiopia.[48] Although genomic tests that can detect this status are available commercially, they are costly and not recommended for general screening.

Frequent breastfeeding the first days following birth is a critical step in establishing lactation, but some women may need analgesic medications that are in the opioid-strength range during this period. Recognizing that the health benefits of breastfeeding are significant and the incidence of morphine overdose in breastfeeding newborns is small, the strategies listed in **Table 33-5** are recommended.[49-51] These guidelines, developed by the Motherrisk Program in Canada,[49] have been shown to reduce the incidence of newborn sedation following maternal use of codeine.[50]

Table 33-5 Strategies for Safe Use of Medications That Contain Codeine During Breastfeeding

Do not prescribe codeine-containing medications if the woman is known to be an ultra-rapid metabolizer for CYP2D6.
Consider prescribing an opioid analgesic other than codeine or tramadol if possible. Several randomized controlled trials have found that nonsteroidal anti-inflammatory drugs are equivalent to codeine with regard to the degree of pain relief reported. The American Academy of Pediatrics' Committee on Drugs states that morphine, hydromorphone, and butorphanol are preferred agents for breastfeeding women who require opioids for pain relief.
If codeine is prescribed:

Use the lowest possible dose that is effective,

Use the medication for the shortest duration possible, and no longer than 4 days. Central nervous system depression worsens in the newborn after 4 days, probably secondary to accumulation of morphine. After 4 days of use, the dose should be decreased or a different medication used.

When codeine causes central nervous system sedation (grogginess, somnolence), the degree of sedation is consistent between the mother and the breastfed infant. Therefore, if the mother shows signs of sedation, the newborn should be examined as well.

Caution women to avoid self-administering additional doses.

Teach women taking these medications about the danger signs in the newborn, which include increased sleepiness (sleeping more than 4 hours at one time), breastfeeding difficulties, limpness, or breathing difficulties.

Notify the infant's care provider that the woman is taking a codeine-containing medication.

Consider genomic testing for individual situations.

Based on Madadi P, Moretti M, Djokanovic N, et al. Guidelines for maternal codeine use during breastfeeding. *Can Fam Physician.* 2009;55:1077-1078[49]; Kelly LE, Chaudhry SA, Rieder MJ, et al. A clinical tool for reducing central nervous system depression among neonates exposed to codeine through breast milk. *PLoS One.* 2013;8(7):e70073.[50]

Populations at risk for being ultra-rapid metabolizers are identified and more information on genomic testing is presented in the *Pharmacotherapeutics* chapter. In addition, women should be instructed that the maximum dosage from all medications containing acetaminophen should not exceed 4000 mg in 24 hours.

Breast Engorgement

Breast engorgement occurs as lactogenesis II starts. This stage begins between 48 and 72 hours after birth in most women, but may not appear until up to 7 days postpartum.[52] It is theorized that engorgement of the breasts is due to a combination of milk accumulation and stasis as well as increased vascularity and congestion. This combination results in further congestion by virtue of lymphatic and venous stasis. Engorgement occurs as the milk supply increases and lasts approximately 24 to 48 hours. The breasts become distended, tense, and tender to the touch. The skin is warm to the touch, with visible veins, and is taut across the breasts. The nipples are firmer and may become difficult for the infant to grasp. Although engorgement is not an inflammatory process, the increased metabolism associated with milk production may cause a mildly elevated temperature. However, a fever of 38.0°C (100.4°F) or higher suggests the presence of mastitis or another infection, as discussed in the *Postpartum Complications* chapter. Women who begin breastfeeding immediately after the birth, nurse frequently on both breasts, and avoid the use of supplements or pumping to express milk for bottle-feeding, are less likely to experience painful engorgement.

Effective treatments for engorgement include application of cold packs, increasing the frequency of nursing, and use of mild analgesics.[53] Application of chilled cabbage leaves has been suggested based on the theory that a substance in the cabbage leaves called sinigrin will relieve engorgement. Studies have not found that cabbage leaves have a therapeutic effect, although application of anything cold will cause vasoconstriction and a reduction in engorgement pain.[53,54]

When a woman is not breastfeeding, comfort measures for engorgement are targeted toward pain relief and cessation of milk production. There are no medications approved for lactation suppression in the United States. Nevertheless, several strategies may be implemented to help with the discomfort and inhibit milk production: the use of good breast support by a supportive bra or breast binder, application of ice packs, and the use of analgesics. These women should use a bra or breast binder to firmly support the breasts, and may be more comfortable if the bra is also worn at night while sleeping. No attempt should be made to express milk from the breasts, either manually or by using heat, as this will simply promote milk ejection (i.e., let-down reflex) and further milk production. For example, the woman should avoid standing in a warm shower and letting the water run over the breasts. When using ice for comfort, caution should be used to not apply the ice directly to the skin. Engorgement will improve within 24 to 48 hours, although the presence of breast milk may take several weeks to resolve completely.

Nipple Pain

Nipple pain and trauma are very common in the initial days postpartum. Nipple pain can lead to discontinuing breastfeeding if untreated. Although most women will experience painful nipples at the onset of nursing that gradually resolve spontaneously, some women will experience blistering, severe pain, or nipples that develop cracks and bleeding. The differential diagnosis includes abnormalities in the way the newborn is positioned or sucking, superficial or ductal fungal infection, and Raynaud's disease. Assessment, diagnosis, and treatment of nipple pain are reviewed in more detail in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

Anhydrous lanolin has historically been recommended for treatment of nipple pain and nipple trauma. More recently, studies have shown that application of breast milk and protection with a breast shield is more effective in healing trauma and mitigating pain than is application of lanolin, which must be wiped away before breastfeeding.[55,56]

Uterine Cramping

Uterine cramping postpartum, commonly referred to as *afterpains*, is caused by the continuing sequential contraction and relaxation of the uterus. Painful cramping is more common in multiparous women and occurs most often during breastfeeding in the first few days after birth. Infant suckling stimulates secretion of oxytocin by the posterior pituitary, which then causes the uterus to contract. Having an empty bladder will lessen uterine cramping because a full bladder displaces the uterus upward, which is associated with more painful contractions. Use of heating pads or lying prone with a pillow or blanket roll under the lower abdomen also may relieve the discomfort of afterbirth pains. NSAIDs are generally very effective for treating uterine cramping and are generally needed for 48 to 72 hours at most.

Perineal Pain

Perineal pain can be treated with nonpharmacologic topical agents, oral analgesics, or topical anesthetics. A helpful toileting technique includes rinsing with warm water from a peri-bottle

during urination, wiping front to back, and patting any incision area dry instead of rubbing or wiping. If perineal discomfort does not progressively improve with time, reexamination should be performed to rule out pathology, including infection.

Ice packs or cold gel packs are most useful for reducing swelling and numbing the perineum in the first 24 hours. All ice packs should be wrapped in a soft covering, with the absorbent side out, for protection against freezing injury; they should not be applied for more than 20 minutes.

Witch hazel compresses may be applied to the perineum or anal area and held in place by the sanitary pad. A 4 × 4 gauze soaked in witch hazel or a ready-to-use commercial witch hazel product may be used. There are no studies that have evaluated the effectiveness of witch hazel. Similarly, the few studies that have compared topical anesthetics or topical anti-inflammatory creams have demonstrated no significant difference between the topical medications and cooling agents.[44,57,58]

When analgesics are needed for perineal pain, NSAIDs provide effective pain relief for most women. Opioid analgesics should be reserved for women whose pain is not well controlled with moderate doses of an NSAID.[44] The constipation that can be caused by opioids can exacerbate perineal pain.

Hemorrhoids and Constipation

Pushing during the second stage of labor can cause hemorrhoids to become edematous and traumatized. The nonpharmacologic comfort techniques listed in **Table 33-6** may be used in combination, except that cold and warm options should not be used during the same time span.

Table 33-6	Comfort Measures for Women with Hemorrhoids
Ice packs	
Cold sitz baths	
Warm water compresses	
Warm sitz baths	
Hemorrhoidal medications:	
Ointments	
Analgesic or anesthetic spray	
Witch hazel compresses (Tucks pads)	
Hydrocortisone suppository	

In addition, a mild stool softener can prevent painful bowel movements that occur when the stool is hard. Increased fluid intake and a high-fiber diet also will promote normal function. Stool softeners or laxatives should be discontinued if the stools become too soft or liquid. Suppositories should be avoided if the woman has sustained a third- or fourth-degree laceration.

Postoperative Care Following Cesarean Birth

While the goals of postpartum care are similar after cesarean birth, some unique circumstances must be considered. In the immediate postoperative period, vital signs, uterine tone, and bleeding are monitored quite frequently. The risk of hemorrhage (intra-abdominal or vaginal) is highest during this initial period. Typically, nursing, anesthesia, and surgical staff care for women during this period. Common postpartum complications associated with cesarean birth are reviewed in the *Postpartum Complications* chapter.

As the effects of regional anesthesia resolve, oral analgesics are used for pain control, the Foley catheter is removed, and ambulation is initiated. Food and fluids can be ingested as tolerated, and intravenous hydration is discontinued when the woman can take sufficient amounts of oral liquids. Care activities are directed toward preventing complications such as deep vein thrombosis, ileus, and endometritis.

The increased risk of deep vein thrombosis in the puerperium is magnified by the woman's immobility after surgery. Strategies to mitigate this risk include pneumatic compression devices until the woman is fully ambulating and initiation of early ambulation. While institutional guidelines may vary, there is no evidence for benefit from withholding food or liquids after cesarean birth.[59] Unrestricted oral intake after cesarean birth accelerates the return of gastrointestinal function, and bowel sounds should be audible within 12 to 24 hours after surgery.

Prophylactic antibiotic therapy is unnecessary after cesarean birth if a single antibiotic dose was administered before the incision is made or after umbilical cord-clamping. Women who were receiving group B *Streptococcus* (GBS) prophylaxis will similarly have this treatment discontinued immediately after surgery. However, if the woman develops chorioamnionitis during labor, antibiotics may be either discontinued immediately after birth or continued until the woman is afebrile for 24 hours, depending on the individual circumstances.

Postpartum anemia is more likely after a cesarean birth, because the typical average blood loss with cesarean birth is 1000 mL. Strategies for pain control after surgery may vary, but the goal is to transition to oral pain medications by the time of discharge. When staples were used to close the abdominal incision, the staples may be removed before discharge from the hospital or at a return visit to an ambulatory site within the first week. Timing of the removal depends on the surgeon's preference and individual risks for wound dehiscence.

A woman usually is discharged from a hospital, assuming no major complications, approximately 48 to 72 hours after the cesarean birth. Recently, some studies have found that the amount of opioid prescribed after cesarean birth at the time of hospital discharge, may exceed the amount needed and consumed.[60] Because approximately 1 in every 300 opioid naïve women prescribed opioids after cesarean become persistent users, it is important to individualize the type of drug and amount ordered in discharge prescriptions.

Postpartum health education should include warning signs for surgical-site infections and appropriate instructions regarding physical activity after major abdominal surgery. These recommendations often include advising the woman to lift nothing heavier than the infant and to avoid other activities that may put excessive strain on the surgical site.

Postoperative Care Following Tubal Ligation

Postpartum tubal sterilization is usually performed the day after a vaginal birth or during a cesarean birth. When a tubal ligation is planned, the woman will be asked to discontinue all oral intake for 6 to 8 hours prior to the sterilization procedure. If an epidural was used during labor or birth, the epidural catheter will be retained in place and used during the sterilization procedure. Typically the surgical incisions for tubal sterilization are small, dressed with simple adhesive bandages, and require no special postoperative care. No additional restrictions or instructions are needed for the postpartum tubal sterilization. Additional information regarding types of sterilization and health education can be found in the *Nonhormonal Contraception* chapter.

Early Postpartum Education

Fatigue, excitement, and feeling overwhelmed may limit the ability of new parents to learn too much new information. Therefore, health education in the early puerperium is prioritized and targeted to the needs of each woman and her family. Assessing the parents' learning needs is the first step. Assumptions may be misleading, such as expecting that a multiparous woman already has a wealth of knowledge about recommended infant care or that a primiparous woman is unfamiliar with personal or neonatal care. It may be helpful to focus on essential topics in discussions, then supplement that verbal health education with written materials or electronic sources and provide contact information for further help in the community. Including available family members in postpartum teaching may maximize the benefits. Recommended patient education topics are listed in **Table 33-7**. Important signs of complications are listed in **Table 33-8**. Discomforts specific to breastfeeding (nipple tenderness and cracked nipples) are discussed in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

Table 33-7	Early Postpartum Education Topics
Physical Care	
Breast care during breastfeeding and engorgement	
Perineal care and pelvic floor exercises (Kegel)	
Activity, exercise, nutrition, and rest	
Hygiene, including tub bath or shower as preferred	
Signs and symptoms of postpartum complications and postpartum mood disorders	
Relational Care	
Emotional self-care (postpartum blues)	
Family planning	
Transitional family relationships	
Partner's needs and fears	
Need for time together with partner and separate from the baby	
Postpartum sexuality	
Sibling rivalry	

Table 33-8	Postpartum Signs of Complications
Woman	
Sudden-onset headache, visual changes, or epigastric pain	
Fever or chills	
Redness, heat, firmness, or pain in one breast	
Increased abdominal pain or vulvar pain	
Excessive vaginal bleeding	
Calf pain, heat, or swelling	
Marked changes in mood	
Newborn	
Feeding difficulties	
Yellowing skin (jaundice)	
Fever	
Inability to console	
Insufficient wet/dirty diapers	
> 6 stools per 24 hours/bloody or very watery stools	
Listless behavior, not alert when awake	
Respiratory difficulties, turning blue	

Pelvic Floor Exercises

Teaching women to perform pelvic floor exercises (also known as Kegel exercises) is another strategy for promoting long-term perineal comfort and strength. Performing pelvic floor exercises has been shown to reduce the prevalence of stress urinary incontinence in women during pregnancy and postpartum[61] and to improve sexual function postpartum.[62] Kegel exercises may also increase circulation to the area, promote healing, restore tone to the pelvic musculature, and facilitate ease of movement. The woman may tighten her perineum, drawing it up and in and maintaining this contracted state while moving in bed or lowering herself onto a chair. For strengthening muscle tone, the exercises can be done in sets of 10, repeatedly tightening and relaxing the muscles for 5 to 10 seconds. It is helpful to repeat these sets two to three times daily—a regimen that will avoid direct pressure to the sensitive areas. If the woman has undergone a mediolateral episiotomy, tightening the muscles when performing Kegel exercises pulls on the posterior end of the suture line because the incision interrupts muscles diagonally and may be too uncomfortable to perform until the perineum is healed.

Sexuality Postpartum

There is wide variation in the time after childbirth that women resume sexual activity with their partners, as well as cultural variations in prescribed waiting times. Factors that are correlated with less sexual activity and dyspareunia include operative vaginal delivery, episiotomy, third- and fourth-degree lacerations, and urinary incontinence.[63] Other circumstances that may interfere with postpartum sexuality are reduced privacy, increased

interruptions, and fatigue. There is no scientific basis for the traditional recommendation to delay sexual activity until the 6-week postpartum examination. Instead, a more nuanced approach is that the woman should wait until she feels comfortable and ready to resume sexual activity. Additional recommendations include using vaginal lubrication, particularly if the woman is lactating; trying alternative positions for comfort during penetrative vaginal intercourse; and engaging in other sexual and nonsexual forms of intimacy.

Contraception

The early postpartum period is an opportune time to explore contraceptive plans with the woman. While sexual activity may be far from the mind of the woman who has recently given birth, as many as 50% of women will have initiated sexual activity by the time they return to an office for the traditional postpartum examination at 6 weeks.[64] In women who are not breastfeeding, ovulation returns at a mean time of 39 days after birth. In breastfeeding women, the return of ovulatory cycles varies a great deal, depending on the duration and frequency of breastfeeding. Although it is not common, approximately 1% to 5% of breastfeeding women who are amenorrheic are ovulatory.[65]

It is best to open the discussion with an inquiry regarding the woman's desire for future pregnancy and perceived need for contraception. Insertion of an intrauterine device (IUD) may be performed safely after delivery of the placenta, although expulsion rates are higher than if insertion is performed earlier than 4 weeks postpartum.[66] Depot medroxyprogesterone acetate (DMPA) may be offered at the time of postpartum discharge. However, because a woman in the postpartum period is still in a state of hypercoagulation, estrogen-containing methods should not be used until at least 3 to 4 weeks postpartum according to the U.S. Medical Eligibility Criteria for Contraceptive Use, although other sources suggest a longer waiting period.[67]

The impact of the woman's lactation status on contraceptive options and timing is controversial. According to the U.S. Medical Eligibility Criteria,[67] lactation is not a contraindication to the use of any contraceptive options. Other authorities warn against the use of combined hormonal contraceptives such as oral contraceptive pills, patches, and vaginal rings because of concerns that these contraceptive methods reduce milk supply. For similar reasons, they may recommend delaying use of high-dose progestins such as DMPA for several weeks.

Another concern is the postpartum use of the progestin-only pill (POP) by Hispanic women who had gestational diabetes. In a study of 904 Latina women, POP use was associated with an almost three times greater risk of developing type 2 diabetes within 2 years relative to use of nonhormonal or combined hormonal contraceptives (adjusted RR, 2.87; 95% CI, 1.57–5.27). This risk increased with duration of uninterrupted use.[67] Additional studies of DMPA among women in this population found an increased risk of developing diabetes, especially for breastfeeding women, but one that was not statistically significant.[67] **Table 33-9** lists the recommendations for contraception for women who are postpartum, including differences based on whether they are breastfeeding.[67]

Table 33-9 U.S. Medical Eligibility Criteria for Postpartum Contraception, 2016

Condition and Subcondition	Copper-IUD	LNG-IUD	Implant	Injection	POP	Combined Pill, Patch, Ring
Postpartum (Including Cesarean Delivery)						
< 10 minutes after delivery of the placenta, breastfeeding	1	2				
< 10 minutes after delivery of the placenta, not breastfeeding	1	1				
10 minutes after delivery of the placenta to < 4 weeks	2	2				
≥ 4 weeks	1	1				
Postpartum sepsis	4	4				
Postpartum, (Breastfeeding)						
< 21 days postpartum			2	2	2	4
21 to < 30 days postpartum with other risk factors for VTE			2	2	2	3
21 to < 30 days postpartum without other risk factors for VTE			2	2	2	3
30–42 days postpartum with other risk factors for VTE			1	1	1	3
30–42 days postpartum without other risk factors for VTE			1	1	1	2
> 42 days postpartum			1	1	1	2
Postpartum (Not Breastfeeding)						
< 21 days			1	1	1	4
21–42 days with other risk factors for VTE			1	1	1	3
21–42 days without other risk factors for VTE			1	1	1	2
> 42 days			1	1	1	1

Abbreviations: IUD, intrauterine device; LNG, levonorgestrel; POP, progestin-only pill; VTE, venous thromboembolism.

Category 1: A condition for which there is no restriction for the use of the contraceptive method.

Category 2: A condition for which the advantages of using the method generally outweigh the theoretical or proven risks.

Category 3: A condition for which the theoretical or proven risks usually outweigh the advantages of using the method.

Category 4: A condition that represents an unacceptable health risk if the contraceptive method is used.

Modified with permission from Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. Medical Eligibility Criteria for Contraceptive Use, 2016. *MMWR Recomm Rep.* 2016;65(RR-3):1-104.[67]

Postpartum Care Plan

The time period between discharge from direct care to a late postpartum office visit can present considerable challenges to women both physically and psychologically. Before the woman is discharged from care given during the early postpartum period, several items should

be reviewed. The woman should have the contact information for a postpartum visit and plan for when that visit will occur. Contraception planning will include education about when to initiate the method, effectiveness, and risks associated with the chosen method. Women who are breastfeeding may need resources such as lactation counseling. In addition, women should be educated about the signs of postpartum depression, and given resources for accessing care if needed. Any pregnancy-related or postpartum complications should be reviewed and plans made as needed for appropriate follow-up.

Mid-Postpartum Period

Historically, the defined endpoint of the puerperium is 6 weeks—a benchmark likely chosen because by that time the woman's uterus has completed its involution to the nonpregnant state. Traditionally, women have not been seen for a healthcare visit during the time period between discharge and 6 weeks postpartum. Women are at risk for a number of complications during that time span,[68-74] yet their interactions with the healthcare system are often fragmented and insufficient. Although both evidence and consensus are lacking regarding the best approach to maternal and newborn follow-up postpartum, the first 6 weeks postpartum should be viewed as a time during which women continue to benefit from intensive contact with healthcare providers. Moreover, the postpartum period overall should be reconceptualized as a process that occurs over the course of a year following childbirth.[75,76]

Care During the First Six Weeks Postpartum

Contact with a midwife or other healthcare provider during the first 6 weeks postpartum may be beneficial for all women. Interval care during this period can be performed in several ways. Some midwives make telephone calls, some do home visits, and others see the woman and/or infant for a 2-week office visit. In addition, some midwives may work with nurses or train birth assistants to initiate the telephone calls or perform the home visits. Many midwives combine these activities depending on the needs of the woman, infant, and family. Office face-to-face visits are recommended for women who had hypertension, a cesarean birth, breastfeeding difficulties, and chronic medical conditions, and for any woman who has an identified risk for developing postpartum depression.[69]

Phone Calls

Using a telephone call to assess the mother–infant dyad's well-being, particularly if the birth occurred in a setting where the family will be alone with their infant shortly after birth, allows the midwife to triage for emergent problems that might require a trip to the office, the pediatric provider's office, or even the emergency department. Telephone calls are usually made the day after the birth or the day after the woman returns home from the birth center or hospital, and again a few days later. During the telephone call, the midwife screens for problems by asking about both maternal and infant well-being. A comprehensive assessment of the woman's condition by telephone may include obtaining her self-report of physical and emotional well-being, breastfeeding success, and coping with the significant family changes associated with childbirth. The midwife should ask about the presence of signs or symptoms for postpartum complications. Content for the phone call is listed in **Table 33-10**.

Table 33-10	Postpartum Telephone Call: Maternal Assessment
System	**Assessment**
General	Food and fluid intake

	Sleep quality and quantity
	Fever or chills
	Headaches
Breasts	Breast engorgement, nipple condition, pain, masses
	Progression from colostrum to milk
	Feeding frequency and success
Abdomen	Abdominal pain, cramping, epigastric pain
	Bowel function, constipation, incontinence
	Urinary pain or incontinence, urgency
Pelvis	Lochia amount, color, and odor
	Perineal pain, swelling, or redness
	Hemorrhoids
Lower extremities	Edema, pain, redness, varicosities
Adjustment	Emotional changes (postpartum blues or depression)
	Coping with life changes and response to newborn
	Social support and help with household chores
	Physical activity level
	Abdominal and perineal exercises
	Family adjustment to newborn
	Confidence in infant care

The telephone call also provides an opportunity to check on the newborn's condition, regardless of whether the midwife is the primary healthcare provider for the newborn. This conversation can be an important opportunity to triage for adequacy of infant feeding and signs of hyperbilirubinemia, infection, or heart disease. Assessment of the newborn by telephone is outlined in **Table 33-11**.

Table 33-11 **Postpartum Telephone Call: Newborn Assessment**

System	Assessment
General	Temperature
	Sleep patterns
	Consolability
	Alert and interacting with parents
Feeding	Frequency and amounts of formula feeding
	Breastfeeding latch, milk supply, frequency
	Infant satisfaction with feeding
Diaper patterns	Frequency of voids and stools
	Appearance of stools
Skin color	Jaundice
	Cyanosis
Umbilicus	Presence of erythema or exudate at umbilical site
	Cord stump fallen off
Circumcision	Appearance of glans if circumcised male

Limitations of postpartum phone calls include the inability to directly screen for neonatal hyperbilirubinemia and excessive infant weight loss and the requirement of reliable telephone service for the woman.

Home Visits

A home visit involves the same evaluations as does a telephone call but also allows the midwife to observe the woman's responses to the infant's needs and cues, the parent–newborn interaction, the place of the newborn in the home's social environment, and resources in the home (e.g., plumbing, water supply, refrigeration, air conditioning/heat, window screens, supplies for baby care). A home visit may also include a brief physical examination of the woman and newborn.

Two-Week Office Visit

Assessments performed at a 2-week visit focus on expected physical, physiologic, and psychological changes in the postpartum period. Particular attention should be paid to how well the woman is coping and an assessment for postpartum depression. A targeted physical examination may be performed as indicated.

If the woman brings her infant to the 2-week visit, the midwife can observe the woman's interaction with her infant and her responsiveness to the infant's needs and cues. Every contact with a new mother is an opportunity to share with her the developmental capabilities of her infant and to discuss safety, infant stimulation, and parenting skills. This is also a good time to verify that the infant either has already seen or has an appointment to see a pediatric healthcare provider and to discuss the need for these visits and for immunizations.

For breastfeeding women, the 2-week visit also can be used as a time to support effective breastfeeding and target any problems. If the woman needs to select a contraceptive method, the 2-week visit is an excellent opportunity to review available options. Many couples will choose to begin sexual intercourse shortly after the woman's lochia resolves, if not before, and women who are formula feeding may ovulate before a routine postpartum physical is performed at 4 to 6 weeks.

Six-Week Postpartum Visit

The exact timing of the postpartum examination is flexible and may be done as early as 4 weeks postpartum. The significance of this office-based visit goes beyond the confirmation of the woman's return to the nonpregnant state. As the final visit related to maternity care, it marks the end of the heightened attention the woman received from the healthcare system during the childbearing year. The idea that the woman's health needs are now met takes a very narrow view of women's health given all the physical, emotional, and social changes that women experience in the first year after giving birth.[69-76] Ideally the postpartum visit will be the beginning of a new phase of supportive health care, rather than merely the end of a maternity package of services. Viewed in this way, the postpartum examination will include each of the

elements described here in addition to the recommended screening and counseling provided during a periodic well woman visit as described in the *Health Promotion Across the Lifespan* chapter.

The 4- to 6-week postpartum consists of a comprehensive history, physical examination, and pelvic examination, as outlined in the Introduction to the Care of Women chapter. Available records of prenatal, intrapartum, and postpartum care during this pregnancy should be reviewed. A description of the procedure for this postpartum visit is presented in Appendix 33B. Topics that should be addressed during this visit are listed in **Table 33-12**.[74-80]

Table 33-12 Topics for 6-Week Postpartum Visit

Topic	Discussion
Review of pregnancy and birth	Provide an opportunity for the woman to ask any questions she has about her experience. If the woman had complications such as gestational diabetes, hypertensive disorders, or preterm birth, she should be counseled that these conditions increase her lifetime risk for cardiometabolic disease.
Complications experienced during pregnancy or birth	Gestational diabetes: Order fasting plasma glucose or 75-g, 2-hour glucose tolerance test. Hypertension, obesity, diabetes, renal disease: Plan for follow-up as indicated. Stillbirth or miscarriage: Visit for review of autopsy findings, emotional support, bereavement counseling as needed.
Postpartum symptoms	Address urinary incontinence, breastfeeding difficulties, dyspareunia, weight loss, smoking cessation, and substance abuse, as indicated.
Reproductive life plan	An interconception interval of 18 months or more is recommended. For women who chose to use a contraceptive method, establish a plan and review the method's effectiveness, instructions, and side effects.
Anticipatory guidance	Nutrition, physical activity, sexuality, returning to work.
Assess for postpartum mood disorders	Use a validated screening tool for postpartum mood disorders that includes screening for anxiety and depression.
Plan for primary care provider and timing of visit	At the end of the postpartum visit, the woman should have a primary care provider identified and recommendations for timing of the next visit.

Management Plans

A review of the prenatal record will identify conditions from the pregnancy that have not resolved. For example, a woman may need follow-up care for an ovarian or renal cyst identified by ultrasound during the pregnancy. Based on the scope of the midwife's practice, follow-up care should be arranged within the service or by referral to another primary care provider. Screening for postpartum depression is recommended for all women who attend a postpartum visit.[81,82]

Based on the history and physical examination, the midwife may be asked to complete an authorization for maternity leave or return to employment. Proper evaluation should include an understanding of the type of work that the woman performs. Midwives are in a position to advocate for women who desire to continue breastfeeding after returning to work and to offer

guidance on strategies to continue lactation.

Women who need contraception should receive necessary prescriptions, appointments, and education. It is not necessary to wait for menses to resume before starting oral contraceptives or inserting an IUD. If the woman has engaged in unprotected penile–vaginal intercourse, use of emergency contraception and/or urine pregnancy testing after 2 weeks of abstinence or condoms can reasonably ensure that the woman is not pregnant. The postpartum visit is also an opportune time to discuss future plans for pregnancy and provide preconception counseling.

Nutrition and exercise are topics of great importance to many women. By 6 weeks postpartum, most women should be physically ready to resume regular exercise routines, in addition to abdominal and pelvic floor exercises to restore tone to those muscle groups most impacted by pregnancy and childbirth. According to the Physical Activity Guidelines for Americans, women should get at least 150 minutes of moderate exercise per week.[83] It may be advisable to gradually increase activity to this level of exercise when reinitiating activity postpartum. Based on limited evidence, there is no concern that exercise or calorie restriction will adversely impact lactation or infant growth.[84,85] Additional recommendations for physical activity can be found in the *Health Promotion Across the Lifespan* chapter.

Many women desire weight loss to return to their prepregnancy weight or to achieve another weight goal. The best way to achieve these goals is through a combination of healthy nutrition and exercise and by identifying what constitutes a healthful weight goal based on body mass index and other factors. Women should be cautioned against rapid weight loss postpartum; a useful reminder is that it took 9 months to gain the weight, so it may take at least the same time to lose it. A detailed discussion regarding dietary recommendations can be found in the *Nutrition* chapter.

The Journey to Parenthood: Psychological Adaptation to Childbearing

Becoming a parent is a complex process through which a woman achieves competence in the role and integrates maternal behaviors into her identify.[86] This process is influenced by many factors. External factors include society's view of motherhood, cultural expectations, and supports or obstacles within the person's personal environment. Many internal factors are involved as well—for example, knowledge, previous exposure to children, the woman's experience in being nurtured, preexisting mental health conditions, relationship status, and personal expectations, to name just a few.[87] Intense emotional feelings, rapid hormonal changes, physical recovery, and fatigue are also part of the postpartum milieu. In this setting, the woman must reconcile her "imagined baby" with the real newborn, get to know and care for the newborn, meet the demands of this 24-hour responsibility, and adapt to her new role as a parent. The postpartum period can be difficult for anyone, but is even more difficult for women who experience a traumatic birth or other trauma. The process is interactive and ongoing.

Midwifery assessment of the process of becoming a parent requires three discrete evaluations: (1) observation of maternal–infant interactions to determine how well maternal–infant attachment is progressing, (2) a review of the woman's environment to identify supports and factors that may impede progress, and (3) a formal assessment for signs of postpartum mood disorders.

This chapter briefly reviews the psychologic process of becoming a mother. Studies of women's experiences postpartum have generally included small samples and different methodologies, which make it difficult to synthesize their results as a body of work. Nevertheless, feelings of fatigue, being overwhelmed, loss of control, and loss of identity are frequently reported.[88] Women's reports of their needs during postpartum consistently refer to four items: (1) more information about their infant, (2) psychological support, (3) a need to share the experience, and (4) practical or material help.[73,89] These four items provide a good framework for midwifery assessment.

Postpartum mood disorders such as anxiety, post-traumatic stress disorder, and depression are inexorably intertwined with preexisting and prenatal mental health conditions. A detailed review of postpartum mood disorders and how to screen for them is presented in the *Mental Health Conditions* chapter, where the reader will also find information about preexisting mental health conditions and prenatal mental health conditions that can have an impact on the postpartum transition.

Traumatic Birth

The events of childbirth are difficult to predict and often do not match the couple's birth plan. Differences between the planned labor and birth and the reality may include use of analgesia or anesthesia, mode of delivery, gender of the newborn, and the quality of support provided in labor. For some families, the experience goes beyond disappointment, as the parents must grieve after a loss. Examples of losses include stillbirth or early neonatal death, loss of

fertility after an emergency hysterectomy, the discovery of congenital birth defects, voluntary or involuntary relinquishment of the newborn to adoptive parents or the legal system, and admission to the neonatal intensive care unit. The couple's grief reactions to these outcomes will be unique to their specific circumstances, coping strategies, and social support.

A traumatic birth places a woman at risk for post-traumatic stress disorder (PTSD). In the Listening to Mothers II national survey of childbirth, 9% of women met diagnostic criteria for PTSD, and 18% of women experienced significant levels of post-traumatic stress symptoms 7 to 18 months after childbirth.[90]

In most situations involving fearful events, the act of listening is by itself therapeutic. After listening to women tell their experiences of birth during the early postpartum period, midwives may identify those who could benefit from formal counseling after traumatic birth. There are mixed results from randomized trials of debriefing after traumatic birth in reducing symptoms of PTSD or postpartum depression. Women most likely to benefit are those who request counseling or already meet some of the criteria for PTSD.[91,92] Conversely, debriefing can cause a reexperience of the trauma and be more harmful than helpful.

Special Considerations

Smoking

While many women are successful in quitting smoking during pregnancy, relapse is common during the postpartum period. In a multistate study using the population-based Pregnancy Risk Assessment Monitoring System (PRAMS), 48% of women resumed smoking within 6 months postpartum, and those women who received smoking cessation interventions in pregnancy were no more successful than the majority of women who had not received prenatal intervention.[93]

Some interventions to help women remain abstinent from smoking have shown promise, although there is no single intervention that is effective for all women. One telephone support program based on motivational interviewing and relapse prevention principles provided phone calls at 3, 6, 9, and 12 weeks and was tested in an RCT. Of the women receiving the intervention, 74% remained abstinent at 12 weeks, compared to 37% in the control group.[94] In a different study, mailing self-help booklets proved helpful in maintaining higher abstinence rates, particularly for low-income women.[95] Midwives should offer women information about available community programs for maintaining abstinence and educate them on the important health benefits of not smoking for themselves and their children. Additional information about strategies used for smoking cessation can be found in the *Health Promotion for Women Across the Lifespan* chapter.

Adolescents

Becoming a parent at a young age may have negative consequences for both the adolescent and infant. Social and economic factors, rather than biology, are likely responsible for these consequences. Adolescents in the postpartum period are more likely than peers who delay pregnancy to experience postpartum depression, lower self-esteem, substance abuse, and poverty. Further, adolescent parents are less likely to attain higher levels of education and are more likely to experience intimate-partner violence than their peers.[96]

A variety of programs exist for providing care to adolescent mothers postpartum. The goals of these programs usually include improvement of the individual's parenting skills, provision of social support, support for educational attainment, and prevention of repeat pregnancy through use of contraception. Programs may be provided in the home, in the community or school, or in clinics.

Many researchers have investigated the ideal method of contraception for adolescents during the postpartum period and have focused on long-term reversible contraceptive (LARC) methods such as intrauterine devices, implants, and injectable progestins. Adolescents who had 3-year etonogestrel implants inserted prior to postpartum discharge if in a hospital or birth center had longer continuation rates and longer delays to next pregnancy compared to those who received IUDs, DMPA, or oral contraceptives.[97]

Transgender Men

Transgender men may have a very different postpartum experience than cisgender women. Ideally, the midwife and the pregnant transgender man will have planned during pregnancy for postpartum care and decision making. Care considerations include increasing the sensitivity and support from hospital or birth center staff, decisions on whether to feed the infant with human milk or formula, and the timing of testosterone therapy.

Transgender men may be more comfortable with referring to lactation as chestfeeding rather than breastfeeding.[14] Transgender men may have had chest surgery such as bilateral mastectomy that reduced or eliminated their ability to lactate. Others may have delayed such surgery until after childbearing or decided not to have surgery. Transgender men may have varying comfort with lactation because of its association with female body function.[98]

Although limited evidence suggests that testosterone is not excreted into human milk,[14,99,100] some transgender men may elect to postpone resumption of testosterone therapy until after weaning. Whether or not the transgender man chooses to lactate, there is no research to suggest the optimal timing for resumption of testosterone therapy.

Transgender men whose sexual partners are biologically male may need contraception.[14,100] Anticipating these clinical decisions and communicating using an open and respectful approach will optimize the individualization of postpartum care for transgender men and their families.

Infant in the Neonatal Intensive Care Unit

Prematurity is the most likely reason for a newborn to need intensive care, with approximately 12% of all newborns being born prematurely in the United States. Other reasons for neonatal intensive care unit (NICU) admission include hyperbilirubinemia, hypoglycemia, infection, meconium aspiration, birth asphyxia, congenital anomalies, and respiratory distress. Having an infant in the NICU can interfere with the developing maternal–newborn attachment through restricted access to the newborn, difficulty in reading the infant's cues, and inability to commit one's time exclusively to the newborn owing to competing demands both at home and at the hospital. The hospitalization of a newborn is associated with high rates of post-traumatic stress and symptoms of depression.[101] Breastfeeding the hospitalized infant is particularly a challenge when the infant is premature and lacks the neuromuscular development to successfully suckle.

Midwives can do much to support these families when the focus of the healthcare team turns toward the fragile infant.[102] Support for the establishment and continuation of breastfeeding includes initiating pumping with a hospital grade mechanical pump within 6 hours of the birth, and continuing to pump milk at least 6 times per day. Milk supplies may be increased by using techniques such as "hands-on pumping." Midwives may advocate for parents to be able to hold their ill infants in skin-to-skin contact even with monitors and ventilation equipment in place.[103] Parents should be monitored for psychological consequences of the infant hospitalization, with attention being paid to their emotional health.

Relinquishment/Adoption of an Infant

Women may relinquish the care of their infant voluntarily through adoption or surrogacy, or

involuntarily through the legal system. Under these circumstances, midwives might be involved in the care of the birth parents, the adoptive or receiving parents, and/or the newborn. The circumstances around the adoption or removal of the infant and emotional reactions are complex and unique to each family.

Support for the woman who gives birth includes providing psychosocial support, therapeutic communication, follow-up services, and advocacy. The midwife can talk with the woman about her emotions in a nonjudgmental way, validating her feelings and acknowledging that feelings may be conflicted. As the woman's advocate, the midwife can ensure that the decision to relinquish an infant for adoption was not coercive except under the condition of legal removal by child protective services. Referrals to social workers and counselors may be offered to address ongoing issues of grief and visitation.

As primary care providers for women, midwives may also be in the position of caring for women who adopt an infant. The decision to adopt often follows failed attempts at getting pregnant and possibly multiple miscarriages. Thus the emotional reaction to adoption can be complex, as these parents struggle with a sense of legitimacy as parents and fear that the infant will be returned to the biological parents. Postpartum depression is possible for women who become mothers by adoption, as they experience stressors similar to those faced by women who have given birth.[104] Women who adopt will likely have educational needs about infant care and may attempt to initiate lactation. Referral to resources and support groups for adoptive families may be helpful.[105] Laws regarding adoption vary according to jurisdiction, so midwives should be aware of credible agencies and attorneys in this field.

Women in Prison

Incarceration presents another circumstance in which the infant will be separated from the woman during the postpartum period. This group of women presents special challenges for the provision of postpartum care due to the likelihood of separation of the infant from the woman when she returns to the correctional facility. Prison nurseries, in which infants are housed with their incarcerated mothers, represent an alternative to the forced separation of infants from their mothers, but relatively few of these special units are available. When prison nurseries are unavailable, community-based residential parenting programs and placement of the infant with relatives are options for continuing the care of the infant within the family.[106,107]

Midwives can advocate for these families and coordinate with prison health providers to provide comprehensive perinatal and postpartum care. While providing care to women who are prisoners, it is important to maintain privacy while in the presence of guards and to avoid the use of restraints for reasons of safety and respect.

Conclusion

The puerperium is a time of great physical and psychological change. Midwives can provide effective care by attending to the woman in the context of her environment, family, and culture. It is important to remember that the postpartum period is not just the end of the childbearing year, but also the beginning of the nonpregnant phase of the woman's life. There is a need to address the high rates of problems such as incontinence, dyspareunia, and depression that can be unintended consequences of otherwise normal pregnancy and childbirth. By moving beyond the care of individual women, midwives can address the health of women in general through advocacy at the system level. In the context of rising healthcare costs and the desire to increase healthcare access to the underserved, there will be new challenges and opportunities for promoting the health of women.

Management of the Fourth Stage of Labor Following Spontaneous Vaginal Birth

IRA KANTROWITZ-GORDON

© hakkiarslan/iStock/Getty Images Plus/Getty

Physical Examination and Management

Vital Signs

Check maternal vital signs every 5 to 15 minutes. If the woman's condition or bleeding pattern changes, assess vital signs more frequently as indicated.

Bleeding

The majority of postpartum hemorrhages occur during the fourth stage of labor. Evaluate vaginal bleeding every 5 to 15 minutes immediately after birth of the infant or more frequently as indicated by changes in the woman's condition and bleeding pattern.

Uterus

Evaluate the uterus for position and tone every 5 to 15 minutes if there is no excessive bleeding that suggests more frequent evaluation.

- *Position*. Assess the uterus by abdominal palpation; it is usually midline in the middle of the abdomen, between the symphysis pubis and the umbilicus. If the uterus is above the umbilicus or significantly deviated to one side of the umbilicus, blood clots may be filling in the uterus or the uterus may be displaced by a full bladder. Evacuation of the uterus or emptying of the bladder should be considered.
- *Tone*. The uterus should be firm to the touch and immediately identifiable. A soft, boggy uterus that is difficult to palpate is not well contracted. Gentle massage of the uterus through the abdomen can promote uterine contraction and should be performed if the

uterus is not firm. Assess for postpartum hemorrhage and presence of blood or clots in the uterus if the uterus does not become firm following abdominal massage.

Bladder

Evaluate the bladder immediately after the third stage and at least 30 minutes after birth for distention and urinary retention. A distended bladder can cause increased uterine bleeding, since the uterus is unable to contract when the bladder is full and displacing it. A woman without regional anesthesia usually can void spontaneously. If she has regional anesthesia, she may need urinary catheterization to empty the bladder.

Perineum

Inspect the vagina and perineum for lacerations, bruising, or early hematoma formation immediately after the birth and after the conclusion of the third stage of labor. Inspect the cervix if indicated. Edema or bruising at the introitus or throughout the perineal area should be noted and documented.

Additional Assessments and Care Practices

- Count needles and gauzes used in the birth to ensure that no gauze is inadvertently left in the vagina and all sharps are disposed of safely. Remove any sharps from the sterile field.
- Clean the woman and bed clothes as needed.
- A perineal pad or ice pack may be placed against the perineum to reduce edema and provide pain relief. An ice pack may be placed next to the perineum intermittently for the first 24 hours after birth.
- Encourage skin-to-skin placement of the neonate following birth, which allows women to notice when their neonates are beginning to root.
- Help the woman position herself to promote infant latch if she plans to breastfeed.
- Assess for comfort. A short period of tremor not associated with infection can be common in the fourth stage of labor and can be relieved with warm blankets, reassurance, and relaxation techniques.
- Assess intake and encourage intake of oral fluids.
- Assess family dynamics.

APPENDIX

33B

History and Physical Examination During the Early Postpartum Period

IRA KANTROWITZ-GORDON

© hakkiarslan/iStock/Getty Images Plus/Getty

Physical examinations during the immediate postpartum period, like any examination, begin with performing a personal greeting, ascertaining if the moment is an appropriate time for the examination, and adapting the environment to provide comfort and privacy. Throughout the examination, the midwife can clarify questions (**Table 33B-1**), integrate teaching, and provide anticipatory guidance.

Table 33B-1	Interval Postpartum History for 6-Week Postpartum Visit
Healthcare encounters	Calls to the midwife or the physician Visits to the hospital emergency department Hospital admissions
Sexual activity	Resumption of sexual activity and number of times Woman's/partner's enjoyment and satisfaction Dyspareunia
Contraception	Contraceptive used or desired Past contraceptive experience
Exercise	Exercise and activities since childbirth Pelvic floor exercises
Vaginal bleeding	Resolution of lochia Episodes of excessive bleeding Resumption of menses
Infant	Attendance at well-child visits Growth and well-being of the infant
Mental health	Signs or symptoms of postpartum mood disorder

Postpartum Physical Examination

Table 33B-2 summarizes the procedure for a postpartum physical examination. The pelvic examination should begin with a visual inspection of the perineum for healing. The bimanual examination will include assessment for vaginal tone by having the woman do a Kegel exercise with one of the examiner's fingers inserted in the vagina. Vaginal walls will be inspected for decreased rugae and atrophy.

Table 33B-2 **Postpartum Physical Examination: Procedure and Expected Findings**

	Procedure	Expected Findings	Deviations from Normal
General	Observe general affect, mobility, and signs of pain or splinting.	Tired, ambulatory without assistance, repeating birth events, usually happy	S: Manner suggesting pain, discomfort, dissatisfaction, unhappiness O: Inability to ambulate without assistance; sad or teary
Vital signs	Assess temperature, blood pressure, pulse, and respiratory rate.	Temperature: normal or low-grade elevation Blood pressure: returns to normal by 24 hours Pulse: 65–80 bpm at rest Respirations: 12–16/min at rest	Temperature: > 38°C (100.4°F) Blood pressure: higher than 140/90 mm Hg or lower than 85/60 mm Hg Pulse: higher than 100 bpm
Neurologic		Oriented to person, place, and time Not in apparent pain Normal reflexes	Disoriented, headache—sudden onset or severe, and/or hyperreflexia Excessively sedated or somnolent, unable to easily awaken Excessive or unexplained pain or restlessness
Thyroid		Normal size and consistency or not palpable	The thyroid gland may be enlarged, indicating postpartum thyroiditis.
Cardiovascular	The examination of the heart and lungs during the early puerperium is performed in the same manner as when the woman is not pregnant or postpartum. Auscultate the heart (rate, rhythm, cardiac sounds). • Systolic ejection murmur persists past the first week of puerperium in 20% of women. • Heart rate decreases to the nonpregnant level within 10 days postpartum.	S: No chest pain. May feel heartbeat increasing with minimal activity O: Regular rate and rhythm	S: Chest pain, palpitations O: Tachycardia
Lungs/ pulmonary	Auscultate the lungs, and percuss as appropriate (the midwife may assist the woman to a sitting position for evaluation of the inferior lobes). • Respiratory volume increases to the nonpregnant rate within the first postpartum week. • Diminished breath sounds or crackles in lung base suggest pulmonary edema or pneumonia.	S: No shortness of breath or difficulty breathing O: Clear to auscultation	S: Shortness of breath O: Adventitious sounds

Breasts[a]	Observe breasts for symmetry. • Palpate to assess engorgement if present. • Palpate axilla to assess for accessory mammary tissue. Inspect the nipple epithelium for erythema, bruising, petechial, and cracks or bleeding. • Observe the integrity of the areola and inspect for blisters or cracks. • Roll or gently squeeze the nipple to assess erectility; express colostrum. • If the woman is not breastfeeding, verify she has a bra that provides comfortable support. • If the woman is breastfeeding, verify adequate bra support. Note: The immediate postpartum period is not a time for a reliable clinical breast examination for cancer screening.	S: Neonate is nursing frequently with a good latch Nipples sore, but not painful Colostrum for 3–5 days with breast fullness before milk is seen O: Soft for 1–2 days; some fullness beginning days 3–5 Nipples intact and erect when stimulated Soft swelling in the axilla may be evidence of accessory mammary tissue that can cause discomfort, but is otherwise benign	S: Neonate is not latching well or frequently Painful nipples No breast filling by days 4–5 O: Nipples: flat, inverted, cracked, bruised, blistered, or bleeding Breasts: erythema, engorged
Abdomen/ gastrointestinal	Examination of the abdomen during the puerperium begins with the uterus, which will be the largest palpable organ. • Position the woman in supine position. • Palpate the fundus abdominally and verify its location. ◆ Immediately after birth, the fundus is several centimeters below the umbilicus. ◆ On the first day postpartum, the fundus slightly relaxes and rises to the level of the umbilicus. ◆ The height of the fundus gradually decreases until it is not palpable abdominally, which usually occurs by approximately 2 weeks postpartum. ◆ Deviations may exist if the woman is at extremes of height or weight. • Palpate the suprapubic area to rule out distended bladder. ◆ There is a high index of suspicion that the bladder is full if the uterus is displaced upward and to one side (generally the right side).	S: Eating and drinking without difficulty. Bowel movements usually return after 2–3 days with normal bowel patterns by 2 weeks. Abdomen: uterine contractions/cramping particularly with nursing O: Abdomen: nontender, nondistended; bowel sounds present; muscle tone is decreased; distension in the first 2–3 days is common, diastasis recti is an expected finding Uterus: fundus firm, nontender, midline, height normal for postpartum day Surgical scar if present is approximated and dry without evidence of infection	S: Nausea or vomiting, abdominal pain, constipation or diarrhea O: Abdomen: distended, tender, or no bowel sounds Uterus: increasing fundal height, deviation from midline, or tender Surgical scar not approximated, surrounded by an area of redness, or discharge present

	• If post cesarean birth, inspect the incision using REEDA for later documentation. • Assess the CVAT. • Request the woman to lift her head onto her chest while the midwife simultaneously palpates the center of the abdomen to assess the degree of separation of the rectus abdominis (rectus diastasis). Determine the size of the separation in centimeters or fingerbreadths for later documentation.		
Urinary	Assess for urinary retention, incontinence, and symptoms of infection.	S: Voiding spontaneously, diuresis, and natriuresis normal, especially between days 2 and 5 Mild external burning, some retention and/or incontinence, and lack of sensation or urge to void are common in the first 2 days postpartum if the woman had epidural analgesia, an operative vaginal birth, or extensive perineal trauma, but should resolve rapidly Tender or sore at area of repair O: Bladder: nondistended—not palpable	S: Pelvic pressure or pain increasing Persistent retention or incontinence O: Bladder: distended Costovertebral angle tenderness
Perineum	Because it is likely that the midwife will come in contact with bodily fluids, most clinicians defer examination of the perineum until after assessment of the woman's extremities. • Obtain adequate visualization (a flashlight, penlight, or flashlight app works well) with good lighting.	Perineum: mild erythema, edema, or bruising may be present Repair: approximated without drainage Lochia: amount decreasing, color, odor	Perineum: increasing tenderness, erythema, edema, bruising Laceration repair: separation of repair, suppuration, or excessive edema, signs of hematoma Lochia: malodor, clots, soaked or overflowing pads

	• Ask the woman to lie on her side: ◆ Choose the side based on the woman's comfort and the layout of the room. ◆ Lateral view and gentle elevation of the upper buttocks allow visualization of the posterior aspect of the repair and the anus. • Observe the woman for discomfort throughout the examination. • Consider use of a large mirror to show the woman her perineum if she desires. • Change to a new pair of nonsterile gloves. • If laceration or episiotomy is present, inspect the full length of the suture line using the REEDA scale for later documentation.[b] ◆ Mild edema is normal in the first 2–3 days postpartum. ◆ If signs of a hematoma are present, use a gloved hand to palpate gently with thumb and forefinger to distinguish between normal edema and hematoma. Signs of hematoma include unilateral labial swelling, black/blueish area of erythema, report of vaginal or rectal pressure, or sudden onset of severe pain. • Evaluate lochia on a sanitary pad, observing the color and extent of saturation and noting the length of time since the pad was changed. ◆ If needed, discard the soiled pad and provide a new one to the woman. • Discard used gloves, and perform hand hygiene.		
Anus	Assess for presence or absence of hemorrhoids.	Normal in appearance Hemorrhoids: pink	Hemorrhoids: deep blue/purple

Lower extremities	Observe for unilateral calf tenderness, erythema, or swelling that may suggest deep vein thrombosis.	S: No pain Generalized muscle soreness O: Edema is common Reflexes normal	S: Pain, aching, or swelling, particularly in one leg O: Deep calf tenderness, one calf larger in the transverse diameter than the other, heat, varicosities that are erythematous and/or painful on palpation
Integument		Normal color No immediate changes. Hyperpigmentation may be retained, but will fade with time. Striae, spider nevi, capillary hemangiomas, varicosities, and skin tags regress but may not completely disappear.	
Laboratory values		Hemoglobin: decreases slightly in the first 24 hours after birth, then plateaus for 4 days, followed by a slow rise to day 14 WBC count: falls to 6000–10,000/mm^3, then returns to normal values by 6 days	A 500-mL blood loss will usually result in approximately a 1-g reduction in hemoglobin or 3% reduction in hematocrit. These values return to normal by 4–6 weeks postpartum.

Abbreviations: CVAT, costovertebral angle for tenderness; O, objective; REEDA, Redness, Ecchymosis, Edema, Discharge/Drainage, and Approximation; S, subjective; WBC, white blood cell.

[a] During the phases of lactogenesis, the breast consistency may be soft, filling (i.e., tense, increasing firmness, slightly enlarged), or engorged (i.e., enlarged, hard, reddened, shiny; skin temperature elevated; painful, dilated veins).

[b] The REEDA scale provides a mnemonic for documentation of healing lacerations or incisions. This midwife-developed instrument was created to provide a standard description of perineal healing, but today it is used widely for documentation of any healing incision. REEDA refers to Redness, Ecchymosis, Edema, Discharge/Drainage, and Approximation. Although a scoring system has been used with this scale in the past, today most midwives use descriptors for each component.[1]

[c] Evaluation of the extremities has traditionally included Homan's sign to assess for deep vein thrombosis (DVT). This test is not diagnostic and could theoretically loosen a thrombus that might be present. Therefore, Homan's sign is not recommended today. DVT is increased 60-fold in the first 3 months postpartum compared with women who are not pregnant or postpartum.[2] Other signs that are more predictive of deep vein thrombosis than a positive Homan's sign include unilateral calf tenderness, erythema, and swelling.

A speculum examination is not necessary unless a Pap test is indicated. Due to the discomfort of the speculum examination, the midwife should wait for complete healing of birth lacerations or episiotomies before inserting a speculum. While minor lacerations may be completely healed, more extensive repairs can take months to fully heal and for pain to resolve. If an intrauterine device was inserted immediately postpartum, then the midwife should inspect for the presence of strings during the speculum or bimanual examination because spontaneous expulsion is more likely.

Before starting the examination:

- Perform hand hygiene, preferably in the woman's sight, and don nonsterile/clean gloves.
- Assist the woman in assuming a comfortable supine or dorsal position.

Laboratory Tests

Laboratory assessment may be required based on history, as indicated in **Table 33B-3**. Under current cervical cytology screening guidelines, women who are at least 21 years old and who do not have a history of abnormal Pap tests need a Pap test every 3 years. Pelvic ultrasound may be indicated for women with complex cysts or other abnormalities identified by ultrasound during pregnancy. Since the postpartum visit marks the end of the childbearing year as well as the continuation of well woman health promotion across the lifespan, recommended screening and counseling for health maintenance, as described in the *Health Promotion Across the Lifespan* chapter, should also be provided as indicated.

Table 33B-3 Postpartum Laboratory Tests

Laboratory Tests	Indications	Timing	Normal Range
Hemoglobin (Hgb) or hematocrit (Hct)	Prenatal anemia, postpartum hemorrhage, cesarean birth	At least 4 weeks postpartum unless symptomatic of acute anemia	Hgb ≥ 12 g/dL Hct ≥ 36%
Thyroid-stimulating hormone (TSH)	Current or recent thyroid disease, history of postpartum thyroiditis, enlarged thyroid, symptoms of postpartum depression	6-week postpartum visit, 3 months and 6 months postpartum	TSH: 0.4–5.0 mU/L
Cervical cytology	Age 21 or older and history of unresolved abnormal cytology or human papillomavirus tests, or 3 years since last test	After perineal and vulvar healing is complete	Negative for intraepithelial lesion or malignancy
Sexually transmitted infection screening (gonorrhea, chlamydia, syphilis, human immunodeficiency virus)	All sexually active women younger than 25 years and women age 25 years and older with a history of sexually transmitted infections, unprotected sexual intercourse, multiple sexual partners in past 12 months	Annually and within 3 months of past infection	Negative
2-hour 75-g glucose challenge	Gestational diabetes Also screen women age 40 years and older with a BMI of 30 or higher	6–12 weeks postpartum and annually thereafter	Fasting glucose < 100 mg/dL 2-hour glucose < 140 mg/dL
Additional Screening Recommended for Health Maintenance[3]			
Alcohol misuse	Screen all women using a validated screening tool and provide counseling and education as described in the *Health Promotion Across the Lifespan* chapter.		
Depression	Screen all women using a validated screening tool and provide management as described in the *Health Promotion Across the Lifespan* and *Postpartum Complications* chapters.		
Intimate partner violence	Screen all women using a validated screening tool as described in the *Health Promotion Across the Lifespan* chapter.		
Lipid disorders	Screen women age 40 years and older using nonfasting or fasting total cholesterol, LDL-C, and HDL-C.		
Tobacco Use	Screen all women using a validated screening tool and provide counseling and education as described in the *Health Promotion Across the Lifespan* chapter.

Introduction

Most women experience an uneventful postpartum recovery (puerperium) while discovering the subtle but extraordinary capabilities of the newborn. Occasionally, however, complications arise that must be recognized and managed promptly.

Approximately 70% of pregnancy-related deaths occur on the day of birth or in early postpartum period.[1] Historically, infection and hemorrhage were the leading causes of postpartum mortality. With the advent of antibiotics, the most frequent causes of death have changed, such that throughout the twentieth century, hemorrhage, hypertension, and thromboembolism were the three leading causes of maternal mortality and morbidity.[1] Today, however, pregnant women are more likely to be older and have chronic health conditions compared to their counterparts in previous generations. The incidence of obesity and cesarean sections has also increased. In the United States, cardiovascular conditions, cardiomyopathy, infection, and hemorrhage are now the four leading causes of pregnancy-related mortality.[1] Approximately 50% of deaths related to pregnancy are preventable.[2] Therefore, it is critical that midwives recognize signs and symptoms of severe maternal morbidity in the postpartum period.[3]

This chapter reviews complications that may occur postpartum after the fourth stage of labor and that may affect the reproductive tract organs. Urinary retention—an early postpartum complication that rarely causes significant morbidity—is presented first. Management of uncomplicated urinary retention is within the midwifery scope of practice. A review of complications associated with severe maternal morbidity or mortality, such as bleeding (e.g., secondary hemorrhage and hematoma), wound complications (seroma, hematoma, dehiscence, and infection), cardiomyopathy, preeclampsia/eclampsia, and thromboembolism, follows. Conditions less often seen in clinical practice, such as postpartum thyroid disorders, are presented last. Immediate postpartum hemorrhage, which occurs during the third stage of labor or in the first hours after birth, is reviewed in the *Third Stage of Labor* chapter. Postpartum mood and anxiety disorders are discussed in the *Mental Health Conditions* chapter, and breastfeeding complications such as mastitis are reviewed in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

Urinary Retention

Postpartum urinary retention can present as the inability to void at all or as covert postpartum urinary retention wherein the woman can void but has a residual bladder volume of more than 150 mL. Urinary retention occurs in approximately 10% of women following vaginal birth, and covert postpartum urinary retention may occur in up to 47% of women.[4,5] Risk factors include epidural analgesia, instrumental delivery, episiotomy, high birth weight, and primiparity.[5,6] Potential causes of urinary retention include slow recovery of sensation after epidural anesthesia, excessive vulvar edema that compresses the urethra, trauma and edema of the bladder neck, and injured bladder innervation. Although long-term adverse effects are rare, urinary retention increases the risk of urinary tract infection and bladder dysfunction in the short term.

Postpartum urinary retention should be suspected when a woman has not urinated in 6 to 8 hours, there is palpable bladder above the symphysis pubis on abdominal examination, the uterine fundus is displaced upward and to the side of the midline, or a full bladder is identified on ultrasound.

Initially, noninvasive care should be implemented to help the woman successfully urinate. Such measures include maintaining privacy, adequate analgesia, warm-water immersion, placement of a few drops of peppermint oil in the toilet water or bedpan, and the sound of running water. Although little research evidence supports the effectiveness of these strategies, they are not harmful. However, if these measures are not immediately successful, urinary catheterization should promptly be used to effectively empty the bladder. Urinary stasis is a risk factor for urinary tract infection and needs to be resolved soon once it is diagnosed.

Urinary retention is usually diagnosed clinically on the basis of history of inability to void and/or abdominal examination to palpate a full bladder. Women who have a palpable full bladder but who are able to void spontaneously should have the amount of voided urine measured; the woman should then be reassessed immediately after voiding to rule out covert postpartum urinary retention. Ultrasound or post-void catheterization can be used to diagnose covert postpartum urinary retention. The treatment of covert postpartum urinary retention is catheterization.

In general, intermittent catheterization is associated with less risk of a catheter-associated urinary tract infection than is placement of an indwelling catheter for individuals with bladder-emptying dysfunction. If an indwelling catheter is used, it should be maintained for the shortest period possible.[7] In this situation, a common approach is to leave the indwelling catheter in place overnight, to be removed in the morning. If the woman is unable to urinate the next day, it may be necessary to leave the catheter in place for a longer period.

Although 150 mL is commonly used as the criterion for diagnosing covert urinary retention, there is no evidence that this cut-off value reflects an increased risk for adverse outcomes. Mulder et al. found that following vaginal birth (n = 439), the mean post-residual void was 140 mL, and that the majority of women with a post-residual volume greater than 150 mL were able to empty the bladder spontaneously by the fourth postpartum day.[5,8] Therefore, reliance on the 150 mL criterion may result in a higher rate of indwelling catheter use than is necessary. Given the lack of clear evidence for a post-residual amount that is associated with adverse

effects, the choice of intermittent versus indwelling catheterization should be individualized.

Figure 34-1 provides a sample algorithm for management of a woman who has postpartum urinary retention. Institutional guidelines will dictate the cut-off values for each step in this algorithm. If a woman is able to successfully void after catheterization, she should be assessed for adequate urinary output for the next two or three occasions to evaluate whether she is still experiencing retention to some degree.

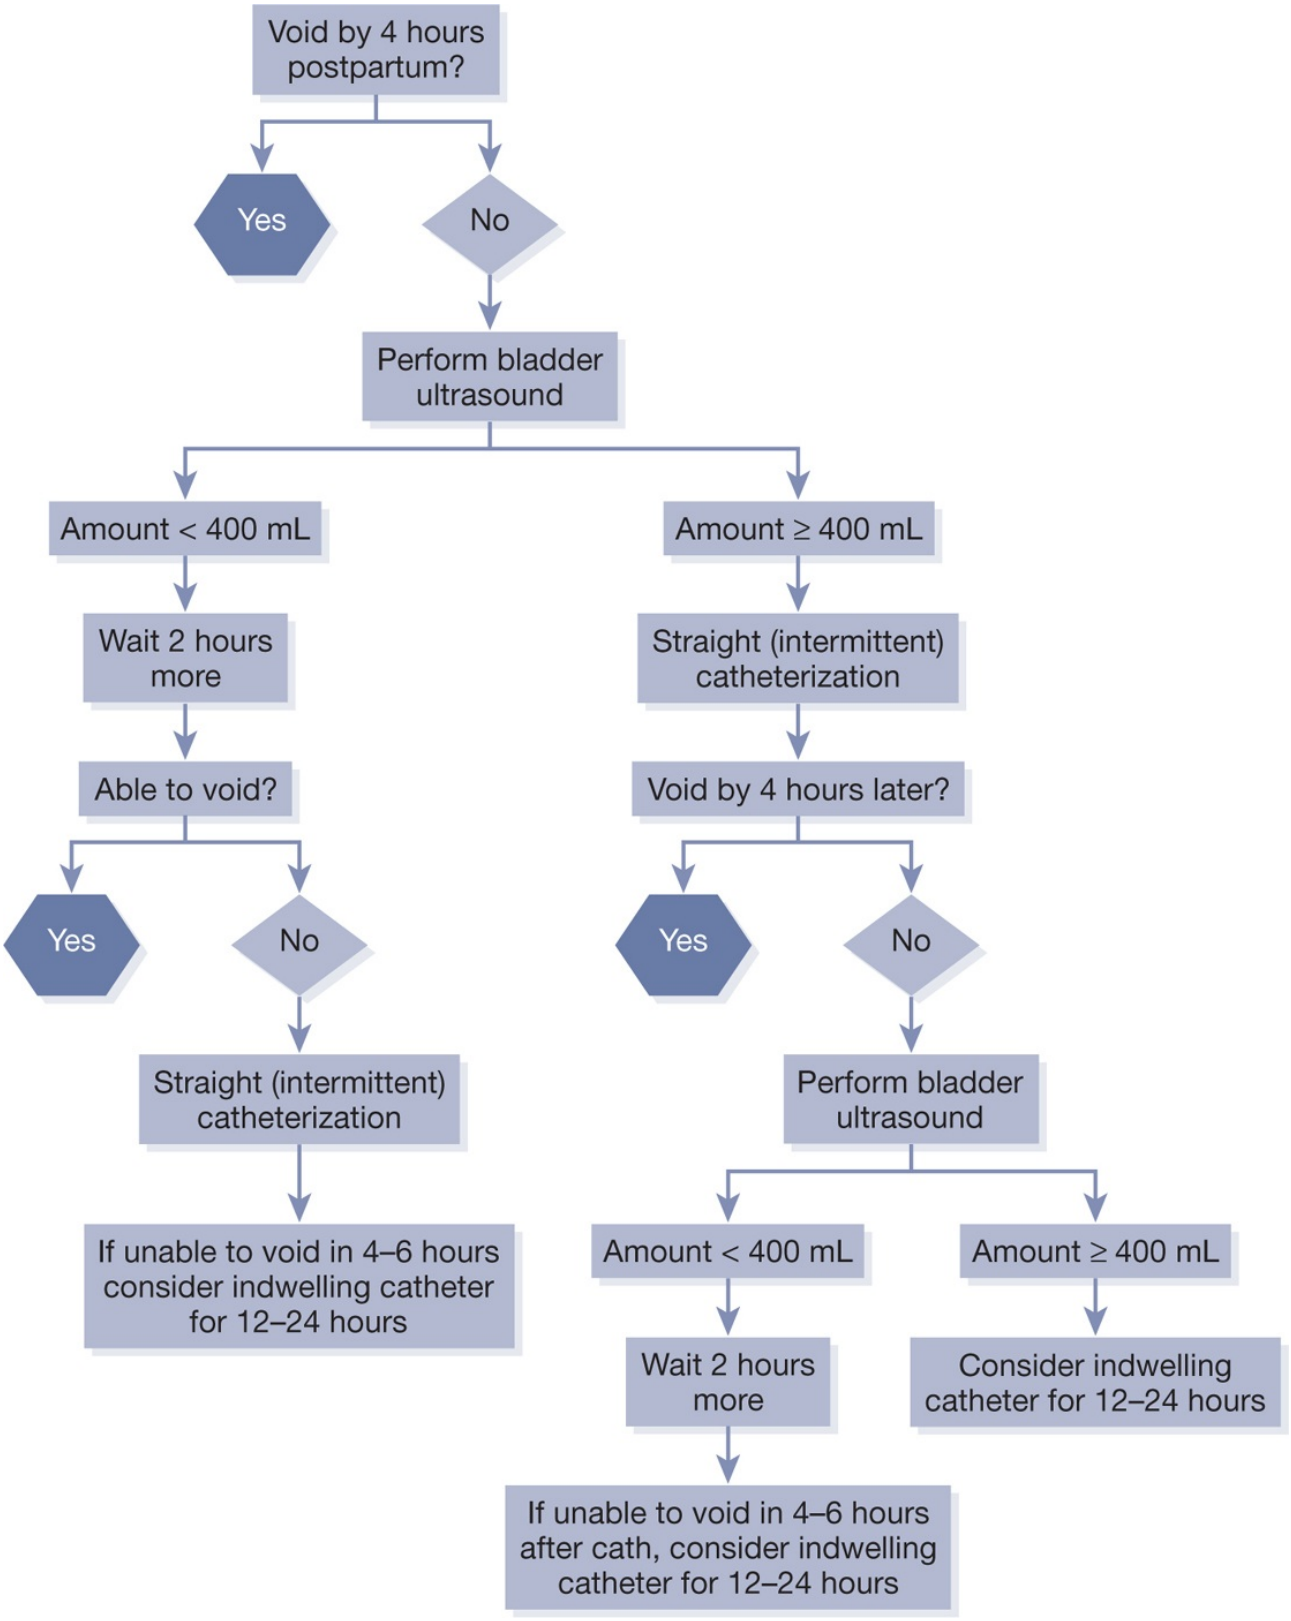

Figure 34-1 Sample algorithm for assessment of voiding and management of urinary retention following vaginal birth.

Puerperal Fever and Puerperal Infection

Puerperal pyrexia or fever is defined as a temperature of 38.0°C (100.4°F) or higher, occurring on any 2 of the first 10 days postpartum excluding the first 24 hours. The first postpartum 24-hour period is excluded because a mild transient temperature elevation can develop as a physiologic reaction to childbirth during this time period. Similarly, a brief temperature elevation of less than 38.0°C occasionally occurs with the onset of milk production 3 to 5 days after birth.

The three most common differential diagnoses associated with postpartum temperature elevations of 38.0°C or more are endometritis, wound infections (e.g., surgical site infection), and urinary tract infections.[9] These three infections account for approximately 31% of hospital readmissions following childbirth in the United States.[10] Less commonly, postpartum fever may be caused by septic pelvic thrombophlebitis, transfusion reactions, or drug reactions. Despite the availability of effective antibiotic therapies, puerperal infections are among the most frequent causes of maternal mortality globally.

Puerperal infection is defined as any infection in the genital tract following childbirth, miscarriage, or pregnancy termination. Organisms that cause puerperal infections include those that normally exist in the lower genital tract or in the bowel, bacteria that are found in the nasopharynx, bacteria that are present on the hands of attending personnel, and those that are present in the air and dust of the environment. Organisms commonly associated with puerperal infection include gram-positive aerobes, such as *Streptococcus* species (A, B, and D), *Enterococcus*, and *Staphylococcus aureus* and *epidermis*; gram-negative aerobes, such as *Escherichia coli*, *Klebsiella*, *Enterobacter*, and *Proteus* species; and gram-variable organisms, such as *Gardnerella vaginalis*. A fever of 39.0°C or higher that develops within 24 hours after a cesarean section may indicate a group A *Streptococcus* infection. Anaerobes associated with puerperal infection include *Peptostreptococcus*, *Peptococcus*, *Bacteroides* species, *Clostridium*, and *Fusobacterium*. Other organisms implicated in puerperal infection include *Mycoplasma*, *Chlamydia*, and *Neisseria gonorrhoeae*.

In addition to the elevated temperature, signs and symptoms of puerperal infection include general malaise, pain, chills, increased pulse, abdominal pain, and possibly malodorous lochia. Because symptoms of puerperal infection are often generalized, the differential diagnosis includes appendicitis, pyelonephritis, and pneumonia. It is important to consider the possibility of extended infections. These infections originate from a localized infection and extend via the path of venous circulation or the lymphatics to produce bacterial infection in more distant sites. Extended sites of puerperal infection include pelvic cellulitis, salpingitis, oophoritis, peritonitis, pelvic and femoral thrombophlebitis, and sepsis.

Physician consultation and/or referral is indicated for women who require evaluation for any postpartum infection.

Endometritis

Uterine infection, which is variously referred to as endometritis or endomyometritis, may occur anywhere within the uterus (i.e., myometrium, endometrium, or both). Endometritis

typically develops within 2 to 4 days postpartum or as late as 2 to 6 weeks postpartum, and can be a mild or a severe infection. This type of infection occurs in 1% to 2% of women following a vaginal birth, approximately 27% in women who have a cesarean birth without administration of prophylactic antibiotics, and 11% in women who are given prophylactic antibiotics before the cesarean section is performed.[11,12] **Table 34-1** lists risk factors for endometritis, with cesarean section being the most important factor putting the woman at risk for this infection.[13] Adverse outcomes associated with endometritis (if not treated) include salpingitis, peritonitis, necrotizing fasciitis, sepsis, septic thrombophlebitis, and death.

Table 34-1 Risk Factors for Postpartum Endometritis

Bacterial Colonization
Bacterial vaginosis
Colonization with group A or B *Streptococcus*
Maternal Characteristics
Obesity
Diabetes
Severe anemia
HIV infection
Pregnancy Characteristics
Preterm birth
Post-term pregnancy
Labor Characteristics
Cesarean section
Chorioamnionitis
Internal monitoring
Manual removal of the placenta
Meconium staining (thick)
Operative vaginal delivery
Prolonged labor
Prolonged rupture of membranes

The classic triad of symptoms associated with endometritis is fever, tachycardia, and uterine tenderness. Women may also experience chills, malaise, foul-smelling lochia, or anorexia. The onset of symptoms varies depending on the infectious organism.

Evaluation includes physical examination to rule out other sources of infection, such as pneumonia, mastitis, pyelonephritis, or surgical site infection. A urine culture will rule out pyelonephritis and chest X ray may be indicated. Endometrial cultures are not obtained because uncontaminated cultures are difficult to obtain. Blood cultures are not routinely recommended if the woman is not acutely ill as most women respond well to empiric therapy. Thus, the diagnosis is generally clinical and based on ruling out other sources of infection.

Consultation should be obtained rapidly for any woman who has signs or symptoms that

indicate she is at risk for severe morbidity, such as hypotension, tachypnea, oxygen saturation of less than 95%, or shortness of breath.

Most endometrial infections are polymicrobial in nature, and frequently include a combination of aerobes and anaerobes from the genital tract. Broad-spectrum antibiotics are the treatment of choice, with several regimens being available. The gold standard is intravenous clindamycin (Cleocin) and gentamicin (Garamycin), administered until the woman is afebrile for 24 to 48 hours.[11] Most women respond to intravenous treatment within 48 to 72 hours and do not require follow-up with oral antibiotics, although oral antibiotics may be recommended for women with acute bacteremia. Women who present with mild endometritis several days after a vaginal birth may be offered oral antibiotics. Intramuscular regimens are available for women in low-resource settings where intravenous treatment is not available.

If the woman is not afebrile after 48 to 72 hours, the most likely problem is resistant organisms such as enterococci, and a change of antibiotic regimen will resolve the infection. In this situation, physician consultation and referral are indicated, as the choice of antibiotic depends on multiple factors including the possibility of other differential diagnoses such as pelvic abscess.

Prevention of Endometritis

Reducing cesarean section rates would significantly lower the rate of postpartum endometritis. Likewise, judicious obstetric practice—that is, prenatal treatment of infections, limited vaginal examinations during labor, avoidance of unnecessary induction of labor, delayed rupture of membranes, and minimal uterine manipulation during birth—can decrease the risk of a woman developing infection postpartum.

One dose of antimicrobial therapy, administered within 60 minutes before a cesarean section is performed, significantly reduces the incidence of endometritis; thus, this has become standard practice in the United States.[14] Vaginal cleansing with chlorhexidine prior to surgery also reduces the incidence of endometritis.[15] Use of traction on the umbilical cord to remove the placenta instead of manual removal is recommended as well.

Wound Complications

Wound complications include infections or dehiscence in a repaired perineal laceration or episiotomy following a vaginal birth, as well as surgical site complications such as seroma, hematoma, dehiscence, and infections in an abdominal incision following a cesarean birth.

Common pathogens associated with wound infections include *S. aureus*, *Streptococcus*, and both aerobic and anaerobic bacilli. The signs and symptoms of infection are similar for both abdominal and perineal wounds. Women usually experience a low-grade temperature, seldom greater than 38.3°C. Localized pain and edema are accompanied by red and inflamed repair edges. Exudate and wound separation or dehiscence may occur as well. Perineal wound infections are often accompanied by dysuria.[13]

Perineal Wound Infection and Laceration Dehiscence

Infection or dehiscence in a perineal laceration or episiotomy repair is generally confined to the skin and subcutaneous tissue. The treatment includes removal of sutures, plus opening, debriding, and cleansing the wound to allow the area to heal by granulation. Physician consultation is indicated. Antibiotics may be administered if cellulitis is present. Most perineal wound infections are not repaired again unless a third- or fourth-degree perineal extension is present. A reduction in the incidence of wound infections has been reported with the administration of prophylactic antimicrobial agents when a third- or fourth-degree laceration occurs.[16]

Surgical Site Complications

Midwives frequently collaborate in the care of women who have a cesarean birth, so they need knowledge of expected findings during recovery from this surgery and signs of surgical complications. Abdominal surgical site infections following cesarean birth usually appear 4 to 7 days after the procedure.

A seroma is a collection of fluid (serum) that appears under the surgical incision. Clear fluid may leak from the incision, and it may appear swollen around the edges. Seromas generally do not need to be treated but are observed carefully to make sure they do not become too large. Occasionally the skin incision is opened in a small area to allow the fluid to drain and/or a drainage tube can be placed temporarily.[17] Similarly, small hematomas usually reabsorb without intervention but larger ones may require evacuation of the clot. Both seromas and hematomas increase the woman's risk of infection. Once such a complication is identified, physician consultation is indicated and the surgical incision is reassessed frequently until it is determined that the seroma or hematoma is not increasing in size.

Surgical site infections can require antibiotics and occasionally drainage. Culture of exudates is not usually required. Reclosure of an abdominal wound may be indicated if dehiscence occurs. Depending on the degree of infection and dehiscence, management may include daily debridement, wound packing, antibiotic treatment, and drainage if necessary. Physician consultation or referral is indicated. If the woman has a persistent fever lasting for 3 or more days, she will be evaluated for complications such as sepsis, septic pelvic thrombophlebitis, abscess, and, rarely, septic shock.

Many techniques can help prevent surgical site infections. In addition to those used to prevent endometritis, such as use of prophylactic antibiotics, other techniques include shaving with clippers, skin cleansing with chlorhexidine (rather than iodine), and skin closure with sutures rather than staples.[17]

Urinary Tract Infection: Pyelonephritis

During postpartum, women are at increased risk for urinary tract infections (UTIs) for several reasons, including trauma to the urethra during birth, urinary retention, and pregnancy-induced dilation of the urethra and ureters. The organisms responsible for UTIs during the puerperium are similar to those observed in nonpregnant women—namely, *Escherichia coli*, which accounts for 80% to 90% of such UTIs, *Proteus mirabilis*, and *Klebsiella pneumoniae*.

Urinary tract infections may cause urinary frequency, urgency, dysuria, and, occasionally, lower abdominal pain. Pyelonephritis is characterized by low-grade fever, flank pain, costovertebral angle tenderness (CVAT), nausea, and vomiting. In contrast, postpartum women with upper or lower tract UTIs often present with fever and generalized symptoms without dysuria, frequency, or urgency. Therefore, any woman with a fever postpartum should be evaluated for a UTI.

Definitive diagnosis of UTI is made by culture of a clean-catch urine specimen that reveals a significant number of a single type of bacteria. Management of UTI and pyelonephritis during the postpartum period is the same as that for primary care outside of pregnancy. Nevertheless, one retrospective cohort review of 256 cases of antepartum pyelonephritis and 23 cases of postpartum pyelonephritis found antepartum and postpartum pyelonephritis to be equally morbid and more debilitating than pyelonephritis outside of the perinatal period.[18] The authors therefore urged prompt diagnosis and treatment of postpartum urinary tract infections.

Postpartum Bleeding Complications

After immediate postpartum hemorrhage, the two bleeding complications most frequently observed in the postpartum period are vulvar hematomas and secondary (late) postpartum hemorrhage, although fortunately, neither are common. Postpartum hemorrhage (PPH) is classified as primary or secondary. Primary hemorrhage occurs within the first 24 hours and is reviewed in the *Third Stage of Labor* chapter. Secondary (late) PPH occurs between 24 hours and 6 to 12 weeks postpartum.[19]

Genital Tract Hematomas

A hematoma is a localized collection of extravasated blood that is usually clotted. The dangers associated with its development include hemorrhage, anemia, and infection. The incidence of postpartum hematoma varies from 1 per 300 to 1 per 1500 births; this condition is most often the result of trauma from instrumental birth or episiotomy.[20] A hematoma arises following spontaneous or traumatic rupture of a blood vessel. Development occurs most often during birth or within a few hours after the birth. The most common sites for hematoma formation include the vulva, the vagina, and the broad ligament (**Figure 34-2**). Because postpartum hematomas vary in size from small to large, some may be overlooked, which could account for the variations in incidence estimates.

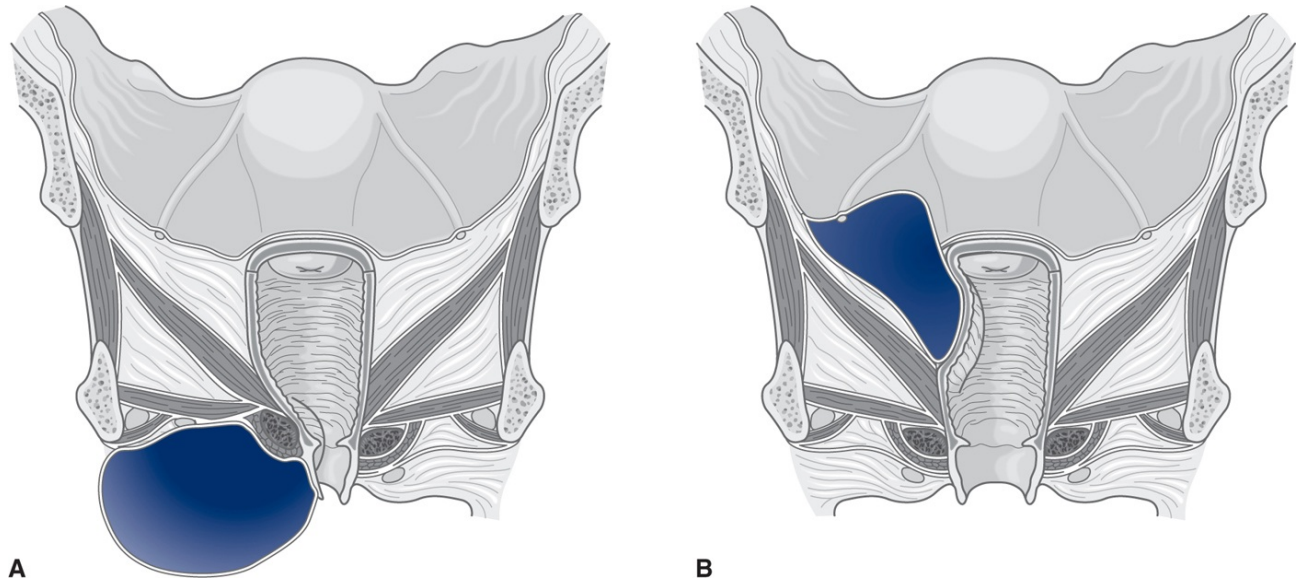

Figure 34-2 **A**. Vulvar hematoma. **B**. Broad ligament hematoma.

Risk factors for postpartum hematoma formation include operative vaginal birth and unrepaired laceration of a torn blood vessel, which can occur during injection of local anesthesia or during repair of a perineal or vaginal laceration. Failure to achieve hemostasis or ligate torn vessels above the vaginal apex prior to repair of an episiotomy or laceration also increases the risk of hematoma formation. Other risk factors include primiparity, multiple

gestation, large fetal weight, preeclampsia, coagulopathies, vulvovaginal varicosities, and prolonged second-stage labor.[20]

Signs and symptoms of vulvar or vaginal hematomas include (1) perineal, vaginal, urethral, bladder, or rectal pressure and severe pain; (2) a tense, fluctuant swelling; and (3) bluish or blue-black discoloration of tissue. The characteristic presentation of a hematoma is extreme pain out of proportion to the expected amount of discomfort and pain for that time period, and pain that develops quite rapidly in the first 2 to 6 hours after birth.[20] Women who have epidural analgesia may report a sudden onset of rectal pressure as the only symptom.

Presenting signs and symptoms of a broad ligament hematoma include lateral uterine pain sensitive to palpation, extension of pain into the flank, a painful swelling identified on high rectal examination, a ridge of tissue just above the pelvic brim extending laterally (i.e., the edge of the swollen broad ligament), and possibly abdominal distension. Subperitoneal hematoma formation—a rare occurrence following vaginal birth—leads to unrestricted bleeding and is typically not recognized until the woman experiences hypovolemic shock.

Vulvar hematomas are the most easily recognizable genital tract hematomas, while vaginal hematomas are generally identifiable when careful inspection and palpation of the vagina and cervix are performed. Small and moderate-sized hematomas may be spontaneously absorbed and managed expectantly. If a vulvar hematoma is small and visible, the edges can be demarcated with a pen, and it can be observed frequently to determine whether it is still growing.

If the hematoma is large or possibly continuing to grow (which indicates active bleeding within the hematoma space), a complete blood count can be ordered as soon as the hematoma is identified and an intravenous line started. Vital signs will need to be monitored frequently to observe for signs of shock, and pain medication prescribed as needed. A physician should be consulted for evaluation and care. Management might include monitoring hematocrit levels, vaginal packing to produce a counterpressure, or an incision to evacuate blood and blood clots and ensure closure of the cavity. The woman with a diagnosis of a hematoma may also need other surgical interventions, such as interventional radiology, blood replacement, or antibiotics.

Secondary Postpartum Hemorrhage

Approximately 1% of women experience a secondary postpartum hemorrhage, with most of these cases occurring within the first 2 weeks postpartum.[19] Common causes of delayed postpartum hemorrhage include uterine subinvolution at the placental site, retained placental fragments or membranes, and endometritis.[21,22] Less common causes include von Willebrand disease (vWD) or other coagulopathies, carcinoma, aneurysms, and arteriovenous malformations. Primary postpartum hemorrhage is a known risk factor for secondary postpartum hemorrhage.[23]

Uterine Subinvolution

The process of uterine involution involves anatomic changes in the size and shape of the uterus

as well as physiologic changes in the endometrial cavity that include involution of the altered spiral arteries that supported the placenta. Thrombus and myometrial smooth muscle contraction initially limit blood loss. The endometrial arteries regenerate their elasticity, shrink, and coil, and the cytotrophoblasts that invaded the endometrial decidua disappear.[21] By approximately 2 weeks postpartum, the uterus can no longer be palpated abdominally, though involution is not typically complete until 6 weeks after birth. When the uterus does not return to its prepregnant size and position within the expected time frame, the term uterine *subinvolution* is used.

The process of involution may be hampered by various factors—most commonly, retained placental fragments, leiomyomas, or infection. Subinvolution of the placental site occurs when the uteroplacental arteries (modified spiral arteries during pregnancy) do not remodel normally. The arteries may become filled with thrombi, have inadequate sloughing, or not regenerate an endothelial lining.[21] New-onset bleeding or hemorrhage as a result of placental site subinvolution most often occurs during the second postpartum week; it can present as an increase or return of lochia rubra or as a frank hemorrhage.[22] Interruption of involution may also occur when maternal activity is excessive; the direct etiology is not clear, but it is postulated that excessive activity might slow the healing process, although there is no direct evidence supporting this theory.

Diagnosis and Management of Postpartum Bleeding

The differential diagnoses for postpartum bleeding initially include placental subinvolution, retained placental fragments, and endometritis. Management depends on the degree of bleeding and whether the woman is hemodynamically stable.

Elements of the woman's history that can help establish a diagnosis are listed in **Table 34-2**. Bimanual pelvic examination findings may include a soft, tender uterus that is larger than expected for the postpartum week. Because retained placental fragments can cause endometritis, however, it is not always easy to differentiate between these two etiologies based on physical examination. Signs of endometritis also include malodorous lochia, tenderness or pain in the adnexa on movement of the uterus, and cervical motion tenderness elicited during a vaginal examination. If retained placental fragments are suspected, ultrasound is indicated. Note that ultrasound does not always provide definitive results, and it may not differentiate between placental fragments and blood clots.[24]

Table 34-2 Evaluation of Postpartum Bleeding

Evaluation	Clinical Considerations
Mode of birth	Retained placental fragments are more common after a vaginal birth; endometritis is more common after cesarean birth
History of menorrhagia or primary postpartum hemorrhage	History of menorrhagia may indicate the presence of a coagulopathy
Current medications	Medications that may predispose the woman to uterine bleeding such as anticoagulants; uterine relaxants

History of vaginal penetration or trauma	Possible new vaginal laceration
Symptoms of infection	Endometritis may present with fever, pain, and malodorous lochia

If the bleeding is heavier than usual but not markedly so, the woman is stable, the uterus has the expected size and shape, and there is no indication of infection or retained placental fragments, then outpatient treatment may begin with ergonovine (Ergotrate) or methylergonovine (Methergine), 0.2 mg by mouth, every 3 to 4 hours for 24 to 48 hours. Women taking either of these uterotonic agents should be informed that bleeding and cramping may increase during the course of therapy.

Physician consultation should be obtained if bleeding is heavy, the woman has signs of infection, or other abnormal findings are noted in the history and physical examination. For example, a history of menorrhagia or previous postpartum hemorrhage may indicate von Willebrand disease, as does the timing of a hemorrhage that occurs between 2 to 5 days postpartum. Preliminary laboratory evaluation includes a complete blood count, platelet count, activated partial thromboplastin time (aPTT), prothrombin time, and fibrinogen levels.[25,26]

Although different subtypes of von Willebrand disease are distinguished, 80% of cases identified during the postpartum period are due to decreased levels of factor VIII. Management depends on the specific subtype. The factor VIII level increases during pregnancy, which usually provides protection from bleeding and consequently is not a concern until approximately 2 days postpartum, when factor VIII levels decrease.[25,26] Postpartum hemorrhage risk secondary to von Willebrand disease persists for as long as 4 months postpartum. Approximately 50% of women with a diagnosis of von Willebrand disease are likely to experience a postpartum hemorrhage.[25,26] The initial evaluation is not directed at diagnosing this disease, but rather at ruling out other causes of bleeding. Other tests that can aid diagnosis include complete blood count and beta human chorionic gonadotropin (beta-hCG).

If infection is present, administration of broad-spectrum antibiotics such as ampicillin–sulbactam or cefoxitin will be recommended. If chlamydia is suspected, azithromycin 1 g orally (one dose) will be added to the regimen. Antibiotics can be administered intravenously or orally depending on the severity of the woman’s symptoms. If retained placental fragments are suspected, curettage may be performed.

Women who experience a sudden, severe delayed postpartum hemorrhage will often present to the emergency department for care. They may need acute care to support their hemodynamic stability.

Preeclampsia/Eclampsia in the Postpartum Period

Hypertension in the postpartum period may represent persistence of hypertension that developed antepartum or intrapartum, or it may be a new-onset condition. Complications of hypertension, which are among the leading causes of severe maternal morbidity and mortality, include cerebral hemorrhage, pulmonary edema, renal failure, hepatic rupture, and death. Approximately 18% of maternal mortality worldwide is secondary to hypertensive disorders of pregnancy, and 75% of maternal deaths that are secondary to hypertension occur after birth.[27,28] Early identification and prompt treatment can significantly reduce the incidence of these complications.[29]

Blood pressure may be transiently elevated postpartum secondary to administration of intravenous fluids or medications, but the presence of neurologic, cardiac, or gastrointestinal symptoms suggests a more serious underlying pathology.[30,31] The differential diagnosis in such cases includes persistence of gestational hypertension or preeclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome, chronic hypertension, new-onset preeclampsia, and, more rarely, cerebral vasoconstriction syndrome, cerebral vascular accident, or hemolytic uremic syndrome.[30,31]

Preeclampsia is often first recognized antepartum or intrapartum, but it can develop de novo in the postpartum period. Approximately 30% of women who develop eclampsia do so in the postpartum period.[31] Postpartum preeclampsia often presents more subtly than onset during the prenatal period. Neurologic indicators (e.g., visual disturbance, headache), nausea, and vomiting appear more frequently during postpartum-onset preeclampsia compared to the prenatal-onset or intrapartum-onset condition.[31] Hypertension and proteinuria are not always present in postpartum preeclampsia and should not be considered the defining symptoms. New-onset late postpartum preeclampsia/eclampsia generally occurs after 48 hours postpartum and prior to 6 weeks postpartum.[31] This type of preeclampsia has been associated with maternal age of 40 years and older, black race, Latina ethnicity, body mass index of 30 or more, and gestational diabetes mellitus.[32]

Maternal blood pressure normally decreases for the first 48 hours postpartum, but then women with preeclampsia will experience an increase to a peak at 3 to 6 days postpartum.[29,31] Thus, women who develop postpartum preeclampsia are often at home when this condition manifests. Early recognition is key to prevention of eclampsia or worsening of the woman's condition—which is why all women should be educated about the signs and symptoms of postpartum preeclampsia prior to being discharged from care.[29] In addition, women who had preeclampsia prior to giving birth should have their blood pressure checked within the first 7 to 10 days after birth.

Physician consultation is indicated for women who have any degree of hypertension postpartum. Those who have mild hypertension (140–150 mm Hg systolic and 90–100 mm Hg diastolic) without any other signs or symptoms of pathology are likely to be treated with oral antihypertensive agents that are compatible with breastfeeding.

Blood pressure measurements exceeding 140/90 mm Hg require immediate assessment for further symptoms. The consensus bundle for severe hypertension during pregnancy and

postpartum developed by the National Partnership for Maternal Safety calls for every perinatal unit to have a protocol that includes notification of a physician or the primary care provider if the systolic blood pressure is 160 mm Hg or higher or the diastolic blood pressure is 110 mm Hg or higher for two measurements within 15 minutes.[29] If a woman being evaluated by a midwife presents with hypertension in these ranges, physician consultation and referral should be obtained quickly, as treatment should be initiated within 60 minutes following the second elevated reading.

Peripartum Cardiomyopathy

Cardiac disorders have not traditionally been a common complication among pregnant or postpartum women. Today, however, cardiovascular disorders account for 15.5% of pregnancy-related deaths in the United States, and cardiomyopathy accounts for 11% of such deaths.[33]

Peripartum cardiomyopathy (PPCM) is a relatively uncommon condition in which a woman develops new heart failure during the last few weeks of pregnancy or the first 5 months postpartum and there is no other identifiable cause.[34],[35] Regionally within the United States and worldwide, large variations are noted in the incidence of this condition. The overall incidence in the United States is 1 in 4000 births, but the incidence of PPCM in southern California is about 1 in 3000 births, and that in Haiti is approximately 1 in 300 births.[36]

For the midwife, care for a woman with PPCM is limited to prompt referral to an appropriate specialist or interdisciplinary care team, preferably including a cardiologist experienced in heart failure.[37] Although care and management of a woman with PPCM are not in the scope of midwifery practice, being able to recognize and refer early can be beneficial for women, as it is sometimes possible for the heart to recover some of its lost function.[34]

The etiology of PPCM remains unknown. Risk factors for this cardiovascular disorder include chronic hypertension, preeclampsia, twin gestation, teenage pregnancy, advanced maternal age, family history of heart failure, and use of tocolytics during pregnancy. One challenge in diagnosing PPCM is that the symptoms are very similar to the normal symptoms seen during pregnancy and in preeclampsia.[37] Fatigue, shortness of breath, edema, and weight gain are symptoms of both PPCM and normal pregnancy, for example. The symptoms most commonly associated with PPCM are marked shortness of breath, orthopnea, tachycardia, palpitations, chest pain, cough, and edema.[38]

The definitive diagnosis of PPCM is made by echocardiogram, but a 12-lead electrocardiogram showing either signs of left ventricular hypertrophy or ST-T wave abnormalities, or a markedly elevated beta natriuretic peptide (BNP) blood test, indicates a strong likelihood of PPCM.[34] Physical examination may reveal crackles in the bases of the lungs, pitting edema, jugular vein distension, a heart sound, or laterally shifted point of maximum impulse when auscultating the heart.[34]

Although PPCM can present during the last few weeks of pregnancy, approximately 75% of women with this condition are diagnosed in the postpartum period.[34] This pattern might indicate that features of PPCM are present during pregnancy, but that women seek help only when the symptoms of shortness of breath, fatigue, and so on do not resolve postpartum.

Women who survive PPCM face many challenges: A strict diet, fluid restriction, and a medication regimen become a daily part of life for many. It is unclear why some women regain their ejection fraction and others do not, but evidence suggests that an ejection fraction remaining greater than 30% for the course of the illness is a key component.[39] In extreme cases, heart transplantation or a surgically implanted mechanical ventricular assist device may be needed for survival.[40]

Vigilance is needed on the part of the midwife to recognize and refer women suspected of

having PPCM. At this time, it is not recommended that women with a history of PPCM become pregnant again, as there is an increased risk of recurrence of PPCM. Nevertheless, this condition is not an absolute contraindication to pregnancy, provided that the ejection fraction has recovered to baseline.

Postpartum Thrombophlebitis and Thromboembolism

Postpartum thrombophlebitis is defined as inflammation of a vein accompanied by formation of a thrombosis (blood clot). Thrombophlebitis can occur in both superficial and deep veins. Thrombosis is more common in women with varicosities and in women who are perhaps genetically susceptible to vein-wall relaxation and venous stasis. Venous thromboembolism (VTE) remains a leading cause of morbidity and mortality in the United States.[1] During the postpartum period, women have a 21.5-fold to 84-fold increased risk for venous thrombosis and embolism compared to nonpregnant women.[41] Results from the Nationwide Inpatient Sample (NIS) revealed a 47% increase in postpartum hospitalizations for VTE between 1994 and 2009.[41] Many thromboembolic events can be anticipated or prevented.

Risk assessment for VTE should begin prior to pregnancy or prenatally. Subsequently, follow-up risk assessment should occur during the intrapartum period and up to 6 weeks postpartum.[42] Nearly half of all pregnancy-related thromboses occur during the puerperium.[43]

Virchow's triad describes the three factors that influence thrombosis formation during pregnancy and postpartum: (1) stasis, (2) hypercoagulable state, and (3) vascular trauma. Venous-wall relaxation resulting from the effects of progesterone and pressure on the veins by the gravid uterus fosters venous stasis. Pregnancy is also a hypercoagulable state, and this state persists throughout the early postpartum period. Venous-wall inflammation and endothelial damage secondary to distension, in the setting of this hypercoagulable state, predisposes the woman to thrombus formation.[44] Prolonged venous compression during positioning for labor or birth may contribute to the problem. Cesarean section also is considered a risk factor for thrombosis; thus, mechanical thromboprophylaxis, such as alternating compression devices, is recommended before and after cesarean birth.

Deep vein thrombosis (DVT) is more common in the left lower extremity (accounting for 70% to 80% of cases), presumably due to compression of the left iliac vein from the gravid uterus and the crossing of the right iliac artery, as well as the nearly 50% decreased blood flow to the lower extremities.[44-47] Women with BMIs of 30 or greater are at higher risk for postpartum and postsurgical thrombus formation than women of lower BMIs; this risk also increases as BMI increases.[48] Daily thromboprophylaxis with low-molecular-weight heparin starting 12 hours post birth or surgery is advised for women with class III obesity (BMI ≥ 40). Weight-based dosage may be more effective as BMI increases than a standard dose of enoxaparin 40 mg daily.[48]

The greatest risk associated with thrombophlebitis is pulmonary embolism.[46] This is true for women who develop DVT, whereas pulmonary embolism is unlikely in women who have a superficial thrombophlebitis. Tachypnea, dyspnea, and sharp chest pain of sudden onset are the symptoms most commonly associated with pulmonary embolism. Sudden onset of these symptoms requires urgent evaluation. Many other, less specific symptoms may be present, including altered lung or heart sounds and apprehension as the woman's blood oxygen level decreases. Under no circumstances should the woman's leg be massaged when thrombophlebitis is suspected. Risk factors for postpartum thrombophlebitis are summarized in **Table 34-3**.

Table 34-3	Risk Factors for Venous Thrombosis
Maternal History–Related Risks	
Obesity	
Smoking	
Age > 35 years	
History of thrombosis

Vascular trauma	
Immobilization	
Postpartum hemorrhage	
Preterm birth	
Stillbirth	

Based on Waldman M, Sheiner E, Sergienko R, Shoham-Vardi I. Can we identify risk factors during pregnancy for thrombo-embolic events during the puerperium and later life? *J Matern Fetal Neonatal Med.* 2015;28(9):1005-1009[45]; American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 84: prevention of deep vein thrombosis and pulmonary embolism. *Obstet Gynecol*. 2007;110:429-440. [Reaffirmed 2016][47]; American College of Obstetricians and Gynecologists. Practice Bulletin No. 156: obesity in pregnancy. *Obstet Gynecol.* 2015;126:e112-e126.[48]

The signs and symptoms of superficial thrombophlebitis and deep vein thrombosis are summarized in **Table 34-4**. DVT presents as unilateral edema and an increase in leg circumference. Tenderness and a feeling of warmth may be noted over the affected veins. Superficial thrombophlebitis is more localized in appearance, but it may be difficult to distinguish between the two conditions based on physical examination.

Table 34-4	Signs and Symptoms of Superficial Thrombophlebitis Versus Deep Vein Thrombosis
Condition	**Signs and Symptoms**
Superficial	Inflammation at the site

thrombophlebitis	Leg pain Localized heat Palpation of a knot or cord, tenderness
Deep vein thrombosis	Abrupt onset with leg pain worsening with motion or when standing Generalized edema of ankle, leg or calf Mild tachycardia and possible slight elevation in temperature Pain with calf pressure Tenderness along course of involved vessel with possible palpable cord

Based on Bennett A, Chunilal S. Diagnosis and management of deep vein thrombosis and pulmonary embolism in pregnancy. *Semin Thromb Hemost.* 2016;42:760-773[46]; American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 84: prevention of deep vein thrombosis and pulmonary embolism. *Obstet Gynecol*. 2007;110:429-440. [Reaffirmed 2016].[47]

The differential diagnosis includes superficial thrombophlebitis versus deep vein thrombosis, muscle strain or trauma, ruptured cyst, vasculitis, and lymphedema. Compression ultrasound is the primary diagnostic test, with or without color Doppler imaging.[49] Diagnostic ultrasound is indicated for DVT as well as for superficial thrombophlebitis to rule out underlying DVT. Laboratory analysis includes high-sensitivity d-dimer studies, which measure fibrin degradation.

Eliciting of Homan's sign (pain on dorsiflexion of the foot) was once thought to be a diagnostic sign of deep vein thrombosis. A positive Homan's sign may, in fact, indicate DVT—but it could also indicate a strained calf muscle. This sign is present in fewer than one-third of women who have a confirmed DVT. Conversely, a negative Homan's sign does not rule out deep vein thrombosis. Furthermore, eliciting Homan's sign could disturb a thrombosis; thus, this test is no longer recommended for evaluation of leg pain in the postpartum period.

Management differs significantly for superficial thrombophlebitis and deep vein thrombosis. Treatment of superficial thrombophlebitis includes leg rest, elevation of the affected extremity, supportive stockings, and nonsteroidal anti-inflammatory drug (NSAID) analgesia as needed. Deep vein thrombosis treatment includes these elements, but adds anticoagulants are added. Ambulation should occur gradually as tolerated. Supportive stockings are recommended. Anticoagulation therapy is usually continued for at least 6 months or longer if needed. Warfarin (Coumadin) is considered safe during lactation. Physician referral is indicated for management of DVT.

Thyroiditis and Thyroid Storm

Some postpartum thyroid disorders may occur slowly and present with subtle symptoms; alternatively, they may develop suddenly as a marked illness. These disorders can occur anytime during the first postpartum year, so symptoms may be remote from childbirth and not identified as a postpartum complication. Postpartum thyroid disease may be difficult to recognize, as symptoms are similar to those commonly encountered in the postpartum period: lack of energy, sleep difficulties, appetite changes, weight changes, memory difficulty, and depressed affect. These symptoms are also found in women with postpartum mood disorders, as discussed in the *Mental Health Conditions* chapter. Postpartum thyroid dysfunction has been associated with postpartum depression.[50] Thyroid illness and mood disorder symptoms are so similar that thyroid-stimulating hormone (TSH) screening is an initial step in the evaluation of postpartum mood disorders.

Postpartum Thyroiditis

Postpartum thyroiditis is an autoimmune thyroiditis that can present as (1) transient hypothyroidism, (2) transient hyperthyroidism, or (3) hyperthyroidism followed by hypothyroidism and then recovery.[51,52] The prevalence varies from 1.1% to 16.7%.[53] Women at increased risk for postpartum thyroiditis include those with gestational diabetes, autoimmune disorders such as type 1 diabetes, previous thyroid dysfunction, and history of thyroid disorders.[54] Although most women recover and are euthyroid within one year, a small proportion of women remain hypothyroid and need long-term replacement therapy.

The clinical course of this disorder starts with thyroid inflammation that damages thyroid follicles. These changes result in excessive thyroid hormone release and hyperthyroidism, which is then followed by transient hypothyroidism once the stores of thyroid hormone are exhausted. Ultimately, the inflammation subsides and thyroid hormone synthesis resumes. The hyperthyroid phase typically occurs around 3 months postpartum and resolves spontaneously within 2 to 3 months.

Signs and symptoms of postpartum thyroiditis resemble common postpartum recovery symptoms. In addition, there is usually no recognizable pain or swelling of the thyroid. Common symptoms of postpartum thyroiditis depend on the phase (hyper or hypo) of the illness. **Table 34-5** compares and contrasts common signs and symptoms of both the hyperthyroidism and hypothyroidism phases of the illness.

Table 34-5 Signs and Symptoms of Postpartum Thyroiditis

Condition	When Condition Manifests	Signs and Symptoms
Hyperthryoiditis	1–4 months postpartum	Anxiety, fatigue, goiter, heat intolerance/sweats, insomnia, irritability, weight loss
Hypothyroiditis	4–8 months postpartum	Constipation, depression, dry skin, fatigue, goiter, impaired concentration

Based on Yalamanchi S, Cooper DS. Thyroid disorders in pregnancy. *Curr Opin Obstet Gynecol.* 2015;27(6):406-415[53]; Carney LA, Quinlan JD, West JM. Thyroid disease in pregnancy. *Am Fam Physician.* 2014;89(4):273-278[54]; Argatska A, Nonchev B, Orbetzova M, Pehlivanov B. Postpartum thyroid dysfunction in women with autoimmune thyroiditis. *Gynecol Endocrinol.* 2016;32(5):379-382.[55]

Because thyroiditis does not become manifest until later in the postpartum period, its symptoms may go unnoticed in either phase of the disorder and misdiagnosis may occur. In the hyperthyroid phase, low levels of TSH, the presence of thyroid peroxidase antibodies, and a lack of TSH receptor antibodies suggest the diagnosis of postpartum thyroiditis. In the hypothyroid phase, an elevated TSH level and a positive test for antithyroid peroxidase antibodies are pathognomonic for this disorder. Postpartum depression and anxiety have similar symptoms, however, and should be included in the differential diagnosis. Women experiencing thyroiditis can have an episode of mild dysphoria that could be mistaken for psychosis.

Treatment depends on the phase and degree of symptoms. If symptoms are mild, no treatment will be instituted. If symptoms of hyperthyroidism are bothersome, beta blockers are the usual treatment of choice, whereas thyroid supplementation with levothyroxine (Synthroid) is prescribed for hypothyroid symptoms.[51,55] Physician consultation or management is indicated. There is no consensus on criteria for treatment, dose of medication, or duration of treatment.

Thyroid Storm

Thyroid storm, also known as clinical thyrotoxicosis, is a rare, life-threatening, acute exacerbation of hyperthyroidism. It occurs earlier than thyroiditis (usually during the first month postpartum) and is distinguished by an abrupt onset of symptoms. This disorder, which results from overproduction of thyroid hormone, is characterized by the sudden onset of a hypermetabolic state. Signs and symptoms include nausea and vomiting, diarrhea, fever (> 41°C), tachycardia, and tremor. Potential outcomes include dehydration, seizures, coma, and death if thyroid storm goes untreated. Increased T_4 levels can lead to cardiomyopathy and heart failure.[56]

The diagnosis of thyroid storm is made clinically, and treatment is initiated prior to obtaining the results of confirmatory laboratory studies. Women in thyroid storm usually present to an emergency department acutely ill and may initially be assumed to have preeclampsia. The presence of neuropsychiatric symptoms and hyperpyrexia distinguish thyroid storm from postpartum preeclampsia or eclampsia.[55] Women in thyroid storm will be hospitalized for intensive care management.

Conclusion

Midwives who are astute in assessing the normal physiology of the puerperium will readily recognize pathologic processes and should be prepared to initiate early treatment and prevent worsening illness. Despite the fact that most postpartum complications require physician management, midwives will typically initiate the diagnostic work-up and recognize occasions when it is appropriate to consult, collaborate, or refer, thereby reducing first-line morbidity and mortality. While physicians medically manage some complications, the midwife will continue to manage other aspects of the woman’s postpartum course and adjustments.

Introduction

Human milk is universally recognized as the unequaled, optimal form of nourishment for infants during the first 6 months to 1 year of life.[1-4] Breastfeeding has numerous health benefits for both a woman and her infant.[5-7] Although breast milk is by far the best nutritional source for infants, a few women cannot breastfeed or choose not to breastfeed. This chapter reviews breastfeeding, contraindications, common problems, management of medications for breastfeeding women, and other infant feeding methods. The term "breast milk" as used throughout this chapter refers to human milk. Commercially or home-prepared breast milk substitutes are colloquially known as formulas and are termed as such throughout this chapter.

Definitions

Research has shown that the key breastfeeding indicators that have clinically significant impacts on health outcomes are exclusivity, duration, and timing of breastfeeding initiation after birth. Although breastfeeding research is hampered by use of a variety of definitions for breastfeeding behaviors, most breastfeeding research uses the 2008 World Health Organization (WHO) definitions, which are presented in **Table 35-1**.[8] In this chapter the term "bottle feeding" denotes use of a bottle containing either breast milk or formula and should not be assumed to be a synonym for breast milk substitutes. The term "chestfeeding" is usually considered more appropriate than "breastfeeding" within the transgender and gender nonconforming (TGNC) community.

Table 35-1 Breastfeeding Terms

Term	Definition
Breastfeeding	Feeding of breast milk (including milk expressed or from a wet nurse). A breastfeeding infant may also ingest any other food or liquids.
Breastfeeding initiation	Breastfeeding of a newborn at least once.
Early initiation of breastfeeding	Provision of mother's milk within the first hour after birth. The World Health Organization (WHO) recommends early initiation of breastfeeding.
Exclusive breastfeeding	Feeding of only breast milk (including milk expressed or from a wet nurse); allows drops, syrups, vitamins, minerals, and medicines but no other substances ingested orally. WHO recommends that infants exclusively breastfeed up to 6 months of age; the American Academy of Pediatrics also recommends exclusive breastfeeding for approximately 6 months.
Predominant breastfeeding	Feeding of breast milk (including milk expressed or from a wet nurse) as the predominant source of nourishment. May include water, water-based drinks, fruit juice, drops, syrups, vitamins, minerals, and medicines, but does not include nonhuman milk or food-based fluids.
Partial or complementary breastfeeding	Feeding of some breast milk in addition to other liquids (e.g., breast milk substitute/formula or milk) and foods.
Breastfeeding duration	The number of days, months, or years that a child receives any breast milk. WHO recommends that breastfeeding continue, with the addition of appropriate complementary (family) foods at around 6 months, for up to 2 years or age or longer, as long as the mother and child desire.

Based on World Health Organization. Indicators for assessing infant and young child feeding practices: Part 1 definitions. 2008. Available at: http://whqlibdoc.who.int/publications/2008/9789241596664_eng.pdf. Accessed August 31, 2017.[8]

Prevalence of Breastfeeding

Among women who gave birth in 2013, 81.1% initiated breastfeeding, more than half (51.8%) were breastfeeding at 6 months, and almost one-third (30.7%) were breastfeeding at 12 months.[9] Despite many national, state, and local initiatives to support breastfeeding, most states are not meeting the *Healthy People 2020* goals for breastfeeding initiation and exclusive breastfeeding at 3 to 6 months.[10] Furthermore, significant racial and ethnic differences in breastfeeding rates are evident. Non-Hispanic black newborns have lower rates of breastfeeding initiation compared to Hispanic and non-Hispanic white newborns (64.3% versus 81.5% and 81.9%, respectively) and lower rates of exclusive breastfeeding through 6 months (14% versus 22.5% and 18.2%, respectively).[11] Because breastfeeding rates decline the most during the first few months after birth, efforts to support women during the early postpartum period are largely focused on this time period.

Lactogenesis and the Composition of Human Milk

Lactogenesis II (also referred to as secretory activation) heralds the onset of copious milk production following childbirth. Lactogenesis II generally occurs 2 to 4 days after delivery of the placenta (60 hours) but may not occur for up to 5 to 7 days postpartum.[12] The physiology of lactogenesis II, which is triggered by the withdrawal of progesterone, is reviewed in detail in the *Anatomy and Physiology of Postpartum* chapter.

Human milk is an individual-specific biofluid that contains multiple bioactive, cellular, and nutritional ingredients (**Figure 35-1**). Approximately 80% of the content of human milk is water. The other 20% consists of a wide range of substances:[13]-[15]

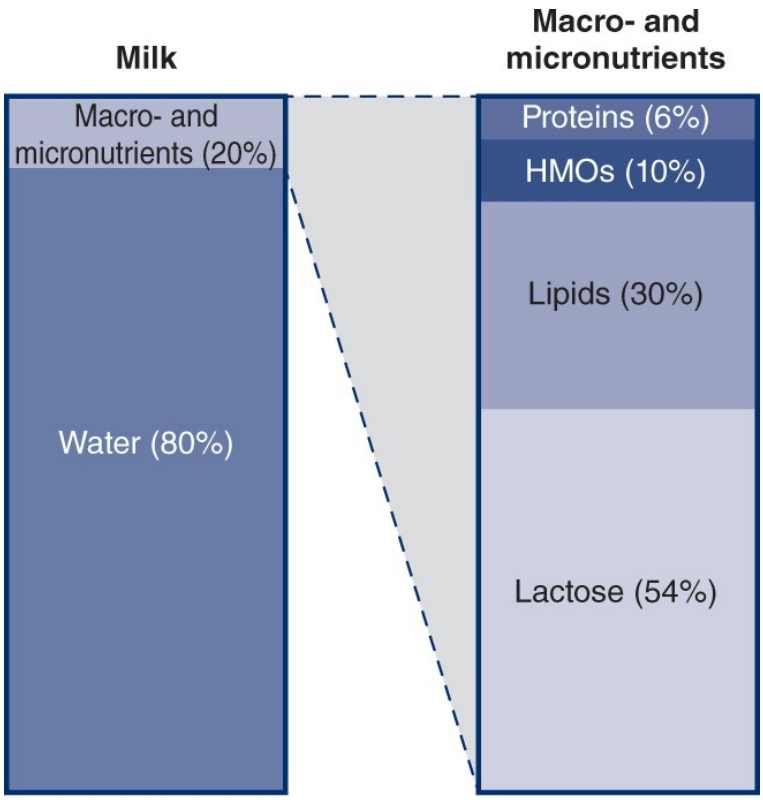

Figure 35-1 Composition of human milk.

Abbreviation: HMOs, human milk oligosaccharides.

Note: Although the percentage of various constituents vary over time and even during the course of a single breastfeeding session, there are > 200 individual bioactive substances that have been identified in human milk.

- Macronutrients: The primary macronutrients in human milk are carbohydrates (predominately lactose), milk fat (lipids), proteins such as whey and casein, and minerals including calcium and phosphorus.
- Micronutrients: Vitamin D and vitamin K are present in constitutionally low levels. Other vitamins vary on the basis of maternal diet.
- Bioactive agents: Substances that can inhibit inflammation and induce antibody responses include growth factors, cells involved in immune response (macrophages, T cells, lymphocytes, leukocytes), cytokines, immunoglobulins (predominately IgA, but also IgG

and IgM), and oligosaccharides.

Both inter-individual and intra-individual variability exist in the composition of human milk. The composition of human milk is affected by a number of factors, including gestational age at the time of birth, time of day, stage of lactogenesis, and maternal environmental factors. The lipid component of human milk is the most variable in terms of concentration.

Human milk is commonly classified as colostrum (prenatal onset of lactogenesis II), transitional milk (2–5 days after birth), and mature milk (lactogenesis II and III). Colostrum contains relatively large quantities of protein and less lactose compared to mature milk. This liquid also contains large quantities of secretory immunoglobulins (IgA), oligosaccharides, and growth hormones. Based on these components, some authors suggest that the primary role of colostrum is immunologic rather than nutritional because the immunoglobulins in colostrum provide a great deal of passive immunity that protects the newborn in several ways. Compared to mature milk, both colostrum and transitional milk have more calories in the form of fat and carbohydrates and appears creamy. Transitional milk is not a discrete entity per se, but rather is the milk produced as colostrum changes to mature milk.

Approximately 24 hours before lactogenesis II is clinically evident, the content of lactate and citrate in breast milk increases, while lesser amounts of sodium and chloride are present. Signs of lactogenesis II include breast fullness, tingling and hardness, leaking, and change of milk color from yellow/creamy to blue/watery.

Mature milk is thinner than transitional milk and has a higher water content. Mature milk is subdivided into foremilk and hindmilk. The foremilk that appears at the beginning of a feed has more carbohydrates, whereas the hindmilk that appears near the end of the feeding session has more fat and lipids.[14] Once lactation is established, women produce approximately 700–800 mL of breast milk per day, although this amount can vary considerably.

The numerous bioactive agents in human milk have remarkable functions that protect and facilitate many aspects of infant health and development. Although a detailed presentation of this interactive physiology between a lactating woman and her breastfed infant is beyond the scope of this chapter, the interested reader can access this material in recent reviews.[16,17]

The Importance of Breastfeeding

Breastfeeding is associated with multiple positive short-term and long-term health outcomes for both the lactating woman and her infant.

The Importance of Breast Milk for the Infant

The body of research that has linked breastfeeding to infant health outcomes is difficult to summarize given the wide diversity of study designs, varied numbers of participants, and presence of confounding social and family factors that can independently affect outcomes. In addition, benefits of breastfeeding are somewhat different in resource-rich versus resource-poor nations.[7] Health benefits that have demonstrated a strong positive dose–response relationship are listed in **Table 35-2** and **Table 35-3**.

Table 35-2	Importance of Breastfeeding for Infants
Benefit	**Percent Lowered Risk (%)**
Any Breastfeeding	
Gastroenteritis	64
Inflammatory bowel disease	31
Obesity	24
Otitis media	23
Type 2 diabetes	40
Sudden infant death syndrome (SIDS)	36 (any breastfeeding > 1 month)
Breastfeeding ≥ 3 Months	
Asthma	26 (if no family history) 40 (if positive family history)
Atopic dermatitis	27 (if no family history) 42 (if positive family history)
Otitis media	50
Type 1 diabetes	30
Breastfeeding > 6 Months	
Acute lymphocytic leukemia (ALL)	20
Recurrent otitis media	77
Upper respiratory tract infection	63

Breastfeeding in the 21st century: epidemiology, mechanisms, and lifelong effect. *Lancet.* 2016;387:475-490.[7]

In resource-poor nations, breastfeeding substantially lowers rates of infant morbidity, infant mortality, gastroenteritis, respiratory disorders, and diarrheal disease.[7] All-cause mortality is increased when infants who are predominately breastfed are compared to those who are exclusively breastfed (relative risk [RR], 1.48; 95% confidence interval [CI], 1.13–1.92), and is much more dramatically increased when infants who are not breastfed are compared to infants who are exclusively breastfed (RR, 14.4; 95% CI, 6.13–33.9).[18] Although the effects on morbidity and mortality are not as striking in resource-rich nations, breastfeeding is clearly protective against gastroenteritis, respiratory disease, asthma, eczema, and allergic rhinitis.[1,7,18,19] A series of meta-analyses summarizing the oral health effects of breastfeeding found that breastfed infants had half the risk of dental caries and half the risk of malocclusions (imperfect positioning of the teeth when the jaws are closed) compared to nonbreastfed peers.[20,21]

Long-term effects of breastfeeding for children are also apparent, although the strength of the etiologic link between breastfeeding and lowered incidence of disease is not fully known for all the associations that have been identified. Children who are formula-fed have higher rates of morbidity and mortality compared to breastfed infants. Children who are breastfed have a lower risk of developing otitis media (recurrent and nonrecurrent), asthma, type 1 and type 2 diabetes, obesity, upper and lower respiratory tract infections, atopic dermatitis, inflammatory bowel disease, celiac disease, gastroenteritis, childhood leukemias, lymphomas, and sudden infant death syndrome (SIDS).[1,7,22-24]

Human milk is even more important for preterm infants. Preterm newborns who do not receive human milk have significantly higher risks of developing necrotizing enterocolitis, neonatal sepsis, metabolic syndrome in adolescence, and hospital readmission. These neonates also have a higher risk for poorer neurodevelopmental outcomes compared to preterm infants fed human milk.[1,6,7,25,26]

The effects of breastfeeding on cognitive development of the child have not been fully determined. Children who were breastfed perform better on intelligence tests as they mature, but these findings may be confounded by caregiver characteristics such as educational attainment, home environmental factors, and socioeconomic factors that are associated with promoting neurodevelopment. To date, studies of neurodevelopmental outcomes of breastfeeding have not generated conclusive results.[27,28]

The Importance of Breastfeeding for the Woman

Breastfeeding also has important health benefits for women. Breastfeeding induces lactational amenorrhea and, therefore, is associated with increased spacing of pregnancies.[5] The duration of lactational amenorrhea and its effectiveness in protecting against conception is related to how often a woman breastfeeds in the first 6 months postpartum. This topic is reviewed in more detail in the *Family Planning* chapter. Immediately after a woman gives birth, breastfeeding accelerates uterine involution via oxytocin secretion and decreases postpartum blood loss. Over the longer term, women who breastfeed have reduced risks for developing several reproductive organ cancers (e.g., breast, endometrial, ovarian), rheumatoid arthritis, type 2 diabetes, hypertension, hyperlipidemia, and cardiovascular disease.[1,5,29-31] In addition, women who do not breastfeed may have a slower return to their prepregnancy weight, although this cannot be generalized to all women given many confounding variables, such as maternal diet choices and maternal body mass index (BMI) prior to and at the birth of the infant.[1,6]

The relationship between breastfeeding and psychological health appears to be bidirectional. Women with prenatal depression are less likely to initiate breastfeeding, and there is a positive relationship between postpartum depression and shorter duration of breastfeeding. Although some studies have found breastfeeding decreases the risk of postpartum depression, others have not confirmed this finding; thus, a clear understanding of the impact of breastfeeding on perinatal mood disorders remains to be elucidated.[32]

It is also important to look at the effects of breastfeeding on the overall maternal–infant relationship. Oxytocin is a potent neuroendocrine peptide that buffers the stress reactivity of the hypothalamic–pituitary axis and enhances maternal–infant bonding.[33,34] The oxytocin secretion stimulated by breastfeeding, therefore, may partly explain the finding of one longitudinal observational study that women who breastfed are less likely to neglect or abuse their child, even after adjusting for confounding variables.[35]

Barriers to Breastfeeding

Formula feeding is costly to both families and society as a whole. The products needed to formula-feed a child are expensive, even when families receive supplemental financial support from the U.S. Department of Agriculture's Women, Infants and Children Supplemental Food Program (WIC). Moreover, the personal and societal costs of treating diseases that are more likely to develop in infants who are not breastfed lends strong support to national and international breastfeeding initiatives. The low rates of breastfeeding in the face of the unambiguous importance of this practice has driven a great deal of research on both barriers to breastfeeding and interventions that can effectively increase breastfeeding rates.[36-38]

Labor and Birth Interventions That Adversely Affect Breastfeeding

Several interventions that may be routinely used or required during labor and birth may have negative effects on subsequent breastfeeding.[39] Many hospital interventions that were standard practices until just a few years ago (e.g., suctioning at birth, routine separation of the maternal–newborn dyad, and provision of pacifiers or supplemental formula) facilitate formula-feeding and lead to lower breastfeeding rates. These hospital interventions are gradually being eliminated as the body of evidence indicating their negative effects on breastfeeding grows.

Epidural Analgesia

All drugs administered to laboring women cross the placenta. Indeed, the presence of epidurally administered anesthetics and opioids can be confirmed (measured) in the umbilical artery and vein after birth.[40,41] Although epidural analgesia is not associated with lower Apgar scores or neurodevelopmental tests in the first 24 hours postpartum,[42] small studies have found that larger exposures to opioids adversely affect breastfeeding initiation.[43] For example, Beilin et al. randomized women who had successfully breastfed their children in the past to differing doses of fentanyl placed in the epidural space for managing labor pain. The women who received the higher dose reported more difficulty establishing breastfeeding and were more likely to discontinue breastfeeding by 6 weeks postpartum when compared to women who did not have fentanyl added to the epidural (17% versus 2%; P =.005). Although this study involved only 107 women, it used a rigorous methodology and its findings support those from a plethora of smaller studies with varied study designs. This association does not mean that opioid exposure *always* adversely affects breastfeeding. Long-term adverse effects on breastfeeding following intrapartum exposure to opioids has not been conclusively demonstrated. Furthermore, these studies did not always control for intrapartum factors other than epidural analgesia that might independently affect breastfeeding success. For example, factors that increase a woman's need for epidural analgesia, such as prolonged labor or malposition may independently have an adverse effect on breastfeeding.

Breastfeeding difficulty in the first days postpartum may have a negligible effect in women with a strong intention to breastfeed, but a much larger adverse effect in women who have other breastfeeding challenges. The most important intervention to ameliorate possible

negative effects of drugs administered during labor is immediate and uninterrupted skin-to-skin contact for at least the first hour after birth, preferably until the newborn moves to the breast and initiates breastfeeding.

Operative Vaginal Birth

Forceps- or vacuum-assisted deliveries can follow long and difficult labors, leaving women exhausted and in pain—conditions that are detrimental to early breastfeeding initiation. Vacuum-assisted birth is associated with cephalohematoma, which may result in newborn pain. Forceps-assisted birth increases the risk of an impaired suckling reflex if the forceps placement bruises the newborn's facial muscles or nerves.[39]

Cesarean Birth

Several retrospective studies have found an association between cesarean birth and lower rates of breastfeeding. It is not known if the surgery itself has an independent effect on breastfeeding or if the indications for the surgery are the most important factors. Women who have a medically indicated cesarean birth are more likely to have experienced a prolonged labor and longer exposure to epidural analgesia, and are more likely to develop chorioamnionitis. Cesarean births are also associated with more blood loss, which may play a role in delayed onset of lactogenesis II. Women who experience this type of an operative birth often have abdominal incisional pain, which can make comfortable positioning for breastfeeding challenging. Moreover, surgically delivered newborns have a higher risk of developing transient tachypnea, which can then interfere with breastfeeding initiation.

Delayed skin-to-skin contact between mother and newborn due to cesarean section interferes with early breastfeeding initiation in the critical first hour after birth. Every effort should be made to initiate early and uninterrupted skin-to-skin contact after cesarean birth in the operating room, or at least in the recovery area.

Practices That Facilitate Breastfeeding

Several clinical interventions for individual women and system-wide policies that facilitate breastfeeding initiation and continuation have been shown to increase breastfeeding rates.

Immediate Skin-to-Skin Contact After Birth

Immediate and uninterrupted skin-to-skin contact after birth significantly increases breastfeeding initiation rates and breastfeeding duration rates.[44] Because the benefits from this practice are so striking, immediate placement of the newborn in a skin-to-skin position on the mother's chest is increasingly standard practice following vaginal birth and is being adopted in many institutions for women undergoing cesarean birth.[45] Skin-to-skin contact for long periods of time is especially beneficial for preterm infants.

The concept of baby-led, mother-guided physiologic breastfeeding refers to maternity care practices that place the mother and infant together with the newborn's hand's free (**Figure 35-2**). The newborn expresses feeding cues, and the mother responds and guides the newborn into feeding positions; the role of the healthcare provider is to support this interaction. This approach contrasts with practices in which the healthcare provider actively places the newborn in a nursing position.[46]

Policies That Facilitate Breastfeeding

In 2011, the U.S. Department of Health and Human Services issued *The Surgeon General's Call to Action to Support Breastfeeding*, a document urging clinicians, employers,

researchers, government leaders, and communities to help women meet the *Healthy People 2020* goals for breastfeeding and their personal breastfeeding goals.[3,10] This document included 20 specific actions to be taken to facilitate this goal, including actions directed toward system-wide improvements (**Table 35-4**). Support for breastfeeding can be organized into several categories, including maternity care practices, professional education, professional support, breastfeeding education, support in the workplace, peer-support programs, and social marketing.

Table 35-4 The Surgeon General's Call to Action to Support Breastfeeding: Actions for Healthcare Providers

1. Ensure that maternity practices around the United States are fully supportive of breastfeeding.
2. Develop systems to guarantee continuity of skilled support for lactation between hospitals and healthcare settings in the community.
3. Provide education and training in breastfeeding for all health professionals who care for women and children.
4. Include basic support for breastfeeding as a standard of care for midwives, obstetricians, family physicians, nurse practitioners, and pediatricians.
5. Ensure access to services provided by international board-certified lactation consultants.
6. Identify and address obstacles to greater availability of safe banked donor milk for fragile infants.

Reproduced with permission from U.S. Department of Health and Human Services. *The Surgeon General's Call to Action to Support Breastfeeding.* Washington, DC: U.S. Department of Health and Human Services, Office of the Surgeon General; 2011. Available at: https://www.surgeongeneral.gov/library/calls/breastfeeding/index.html. Accessed August 28, 2017.[3]

Federal support for breastfeeding echoes multiple position statements and recommendations from maternal and child health organizations, including the U.S. Preventive Services Task Force (USPSTF)[36]; the Centers for Disease Control and Prevention[37]; the American Academy of Pediatrics (AAP)[1]; the American College of Nurse-Midwives (ACNM)[4]; and the American College of Obstetricians and Gynecologists.[47] Each of these organizations recognizes breast milk as the "optimal infant nutrition."

Telelactation, in which a woman receives support from a lactation consultant via two-way video on personal mobile devices, is drawing increased interest as well. Such services may offer support 24 hours per day for a fee or monthly subscription.[48]

One of the most well-known interventions designed to facilitate breastfeeding is the global Baby-Friendly Hospital Initiative, launched by the World Health Organization and United Nations Children's Fund.[38] Hospitals that successfully implement the 10 steps outlined in the Baby-Friendly Hospital Initiative are awarded a special designation. The 10 steps focus on maternity care practices and hospital policies that are known to promote breastfeeding duration. Research on the breastfeeding outcomes associated with the Baby-Friendly Hospital Initiative has used multiple methodologies, designs, and populations. This heterogeneity makes it difficult to assess the body of literature. In short, research on the Baby-Friendly Hospital Initiative appears to improve breastfeeding duration and breastfeeding exclusivity but the

effect of this package of interventions on breastfeeding initiation has not been clearly established.[49] More information about the Baby-Friendly Hospital Initiative and effective breastfeeding interventions can be found in the Resources section at the end of this chapter.

Contraindications to Breastfeeding

While uncommon, some situations and conditions make breastfeeding inadvisable. Maternal and neonatal medical conditions in which breastfeeding is contraindicated are listed in **Table 35-5.**[1,38,50-53]

Table 35-5	Conditions in Which Breastfeeding Is Contraindicated or Should Be Temporarily Suspended
Disease/Disorder/Medication	**Breastfeeding Recommendation**
Neonatal Disorders	
Galactosemia	Contraindicated
Glucose-6-phosphate dehydrogenase (G6PD) deficiency	If breastfeeding, the woman should avoid fava beans, nitrofurantoin, primaquine, and phenazopyridine to avoid inducing hemolysis in the infant
Phenylketonuria	May partially breastfeed if this practice is alternated with modified formula feeding and monitored
Maternal Infectious Diseases	
Brucellosis, untreated	Contraindicated
Cytomegalovirus	Individualized based on infant circumstances
Herpes, active lesion on breast	Infant may be given expressed breast milk, as the infectious agent is not transmitted through breast milk
Human immunodeficiency virus (HIV) positive	Developed nations: Contraindicated Developing nations: Benefits of breastfeeding may outweigh risk of infection
Human T-cell lymphotropic virus (HTLV) 1 or 2 infection	Contraindicated
Maternal Infectious Diseases	
Influenza, H1N1	Separate infant and mother if possible Infant may be given expressed breast milk, as the infectious agent is not transmitted through breast milk
Tuberculosis, untreated	Infant may be given expressed breast milk, as the infectious agent is not transmitted through breast milk
Varicella, if infection develops 5 days before birth to 2 days after birth	Separate infant and mother Infant may be given expressed breast milk, as the infectious agent is not transmitted through breast milk
Maternal Medications[a,b]	
Alcohol	Occasional alcohol use is acceptable, but avoid nursing for 2 hours after drinking
Amiodarone (Cordarone)	Contraindicated; may cause infant hypothyroidism
Anticonvulsants	Phenobarbital (Luminal), ethosuximide (Zarontin), and primidone (Mysoline) can have high concentrations in breast milk and may cause infant sedation; physician consultation is recommended for women who need any anticonvulsant medication
Antiretroviral medications	Contraindicated
Chemotherapy agents for cancer (e.g., antimetabolites that interfere with DNA	Discontinue breastfeeding for as long as these agents are in breast milk

replication and cell division such as methotrexate)	
Chloramphenicol (Chloromycetin)	Requires close monitoring of blood levels in the woman and infant to prevent bone marrow suppression
Codeine or tramadol-containing analgesics	FDA recommends that breastfeeding women not use codeine-containing medications or tramadol.[51] ACOG states codeine-containing drugs and tramadol may be used if needed in the first postpartum period. If an opioid is required, use the lowest dose possible and monitor the breastfed infant for signs of toxicity.[51] Contraindicated if the woman is known ultra-metabolizer
Cyclosporine (Neoral)	Requires close monitoring of blood levels in the woman and infant
Drugs of abuse	Cocaine, heroin, and marijuana are found in high concentrations in breast milk and associated with delays in infant development
Ergotamines (e.g., dihydroergotamine [Migranal])	Contraindicated
Iodine	Can cause hypothyroidism in infant
Metronidazole (Flagyl)	Controversial. Metronidazole (Flagyl) is excreted into breast milk in relatively high concentrations—approximately 20% of the maternal dose. This drug is a known mutagenic agent in animals. The American Academy of Pediatrics recommends discontinuing breastfeeding for 12–24 hours after a single 2-g maternal dose. Other authors have stated doses in the range of 200–400 mg/dose are compatible with breastfeeding. There are no reports of adverse effects on breastfeeding infants.
Lithium (Lithobid)	Requires close monitoring of blood levels in the woman and infant
Maternal Medications[a,b]	
Radiation therapy (requires temporary cessation)	Discontinue breastfeeding for as long as radioactivity is in breast milk
Retinoids (e.g., isotretinoin [Accutane])	Contraindicated
Statins (e.g., simvastatin [Zocor])	Contraindicated
Sulfa (e.g., sulfamethoxazole [Bactrim])	Should be avoided if the infant is premature, jaundiced, or has G6PD deficiency

Abbreviations: ACOG, American College of Obstetricians and Gynecologists; FDA, U.S. Food and Drug Administration.

[a] This table is not comprehensive. Access current information about breastfeeding effects of drugs not on this list at the National Library of Medicine's LactMed website (https://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm).

[b] Additional medications for which the effects on a breastfed infant are unknown include anxiolytics such as lorazepam (Ativan), antipsychotics, and antidepressants.

chemicals into human milk. *Pediatrics.* 2001;108(3):776-789.[53]

Alcohol, Tobacco, and Marijuana

Little recent research has reviewed tobacco use and breastfeeding. The Centers for Disease Control and Prevention (CDC) and other professional organizations recommend that women breastfeed even if they continue smoking during pregnancy or restart tobacco use after birth. Although nicotine is found in breast milk, no studies attribute infant health problems to maternal tobacco use during breastfeeding. If a woman does plan to smoke, she is advised to smoke after breastfeeding and to smoke outside the home to limit the infant's exposure to secondhand smoke, which is known to have detrimental health effects.

The effects of alcohol use during pregnancy are well documented. but few studies have examined alcohol use during breastfeeding. Alcohol diffuses easily into breast milk, such that concentrations approximate maternal blood alcohol level. Alcohol inhibits the milk ejection reflex, temporarily decreasing milk production. Women are advised to wait approximately 2 hours after consuming alcohol before breastfeeding or to wait to partake of alcohol until just after breastfeeding.[54]

Marijuana increasingly is available for medicinal or recreational use. Because marijuana has been legalized for recreational use in some states, women may equate marijuana with alcohol and consider it safe to use during breastfeeding. Marijuana is lipophilic and accumulates in breast milk very easily. Moderate amounts of delta-9-tetrahydrocannabinol (THC) have been found in breast milk.[55] Few studies have followed infants of breastfeeding women who regularly use marijuana; however, extrapolation of data following in utero exposure and data on the effects of marijuana on adult brains suggest that marijuana use is not recommended for women who are breastfeeding.[55]

Pharmaceuticals and Breastfeeding

When considering use of drugs in pregnancy, four key questions need to be considered: (1) How much of the drug transfers into breast milk? (2) If the drug does transfer to breast milk, does it have an adverse effect on the infant such that it is contraindicated or must be used with specific cautions? (3) Does the drug inhibit breast milk production? and (4) Is the drug a galactagogue (an agent that stimulates breast milk production)? The principles of prescribing and basic pharmacokinetic and pharmacodynamic considerations for medications are reviewed in the *Pharmacotherapeutics* chapter. Website resources for assessing the safety of pharmaceutical use during lactation are listed in the Resources section at the end of this chapter.

Transfer of Drugs into Breast Milk

Alveolar lactocyte cells line the alveoli that make up the glandular secretory tissue within the breast. During the first few weeks after birth, large gaps exist between alveolar cells in the maternal breast alveoli, facilitating easy transfer of various agents, including immunoglobulins. As milk production is established and the alveolar cells expand, the intracellular gaps close, so that drug transfer becomes more difficult.

Several pharmacologic relationships play key roles in drug transfer into breast milk:[56]

- Drugs that are highly bound to plasma proteins, such as ibuprofen (Advil), are less likely to transfer to breast milk compared to drugs that are less protein-bound.
- Drugs that move from plasma to tissue rapidly reduce the free drug concentration in plasma, thereby lowering the chance of diffusion into breast milk. Methylprednisolone (Medrol), for example, works within cells and quickly moves into maternal tissue.
- Highly lipid-soluble drugs pass easily into breast milk and may accumulate in milk fat. Opioids, for example, may be found in high concentrations in breast milk.
- High-molecular-weight molecules such as heparin and insulin do not pass easily into breast milk.
- Some drugs cross membranes in their un-ionized form. Breast milk is slightly acidic compared to plasma, allowing highly basic drugs to be ionized and concentrated in breast milk. Thus, weak bases such as codeine and oxycodone may become ionized in breast milk and "trapped" in the milk, further increasing their concentrations in breast.
- Active transport is used by a small number of drugs (e.g., ranitidine [Zantac], nitrofurantoin [Macrobid], acyclovir [Zovirax]).

The method of calculating breast milk concentrations of drugs that is the most clinically useful is the relative infant dose (RID). The RID is the maximum percentage of the maternal dose that the infant consumes assuming a milk intake of approximately 150 mL/kg/day and a standard therapeutic maternal dose. An RID of less than 10% is considered safe for healthy term infants.[56] The National Library of Medicine's LactMed Database uses the RID calculation. Information about LactMed and RID calculations can be found in the Resources

section at the end of this chapter.

Fortunately, most drugs commonly used by lactating women are compatible with breastfeeding. Although more research is needed regarding many agents, drug transfer is rarely a reason to discontinue breastfeeding, and the midwife should be encouraged to seek out the most current and reliable information when counseling a woman about the safety of this practice. **Table 35-6** summarizes guidelines for breastfeeding and the use of medications.

Table 35-6 **General Guidelines for Breastfeeding and Medication Use**

1. Use pharmaceuticals only when necessary.
2. Use the smallest therapeutic dose for the shortest time that is effective.
3. Whenever possible, choose an agent with a short half-life, an agent with a relative infant dose that is less than 10%, and an agent that is not delivered by sustained release.
4. Arrange the timing of drug dosing so that it is given immediately after nursing or before the infant has a long sleep period.
5. If the drug is contraindicated for infant exposure, pumping and discarding the breast milk may be necessary.
6. It is rare that a medication is a reason to discontinue breastfeeding.

Drugs That Are Contraindicated During Breastfeeding

In 2001, the American Academy of Pediatrics Committee on Drugs published an evidence-based listing of drug information for breastfeeding.[53] This document has stood the test of time and is still considered one of the most evidence-based resources for use of drugs by breastfeeding women. The 2013 update to this document expanded on selected topics such as antidepressants, illicit drugs, analgesics, and vaccines. Table 35-5 summarizes the considerations for the drugs that are most commonly encountered in primary care and are contraindicated during breastfeeding, as well as the drugs that may be used with specific cautions.[38,55-59]

Drugs That Inhibit Milk Production

It has long been believed that contraceptive doses of estrogens suppress milk production. However, research has shown that estrogen doses greater than 30 mcg per day are needed to suppress lactation; the doses in current contraceptive formulations are likely to be smaller than this amount, so they are not associated with lactation suppression. The current CDC guidelines for use of estrogen-containing contraceptive products by breastfeeding women are listed in the *Postpartum Care* chapter.[60] These recommendations reflect the results of a detailed expert review of this literature that included consideration of the importance of breastfeeding and the theoretical risks of estrogen and progesterone in relation to the timing of lactogenesis. **Table 35-7** lists drugs that may inhibit breast milk production.

Table 35-7	Drugs That May Inhibit Breast Milk Production

Generic (Brand)
Bromocriptine (Parlodel)
Cabergoline (Dostinex)
Estrogen-containing contraceptives[a]
Ergotamine (Cafergot)
Progestins[a]
Pseudoephedrine (Sudafed)
Testosterone
Tamoxifen (Nolvadex) and other estrogen-receptor blockers

[a] See the CDC medical eligibility criteria for timing of initiation of estrogen or progestin containing contraceptives: Curtis KM, Tepper NK, Jatlaoui TC, et al. U.S. medical eligibility criteria for contraceptive use, 2016. *MMWR Recomm Rep.* 2016;65(RR-3):1-104.[60]

In the past, drugs such as bromocriptine (Parlodel) that inhibit milk production were used to suppress lactation for women who cannot or chose not to breastfeed. The evidence for effectiveness for these agents is weak, however, and possible adverse effects have not been well characterized. These agents are not recommended for use in clinical practice.[61] Nonpharmacologic methods to ease the comfort of breast engorgement include breast binding, wearing a tight brassiere, and ice packs.

Galactagogues

When lactogenesis is not well established and conservative management techniques have failed to increase milk supply, *galactagogues*—drugs that can stimulate breast milk production—may be considered. Pharmaceutical galactagogues are dopamine antagonists that increase prolactin levels.[62] The evidence for effectiveness of galactagogues is limited, however, and they should be used cautiously given the possible side effects associated with use of these drugs.

Domperidone has been shown to significantly increase milk production, but is not available in the United States. The Food and Drug Administration (FDA) has recommended that domperidone not be used because it can cause QT-segment elevation on electrocardiogram during intravenous therapy, which in rare cases may be fatal.[63]

Metoclopramide (Reglan) is a dopamine antagonist used for gastrointestinal indications. A side effect of the drug is galactorrhea; thus, it is used on an off-label basis to help women increase their milk supply. Metoclopramide has a number of possible side effects, including fatigue, mental exhaustion, and extrapyramidal effects, so it should be used for only a limited time.[64] More severe side effects of this agent include tardive dyskinesia (involuntary repetitive movements such as grimacing) and dystonia, which warranted the FDA “black box” warning on the drug’s label, advising against prolonged use or high doses of the drug. Metoclopramide has not been shown to be more effective than a placebo.[64]

Herbal galactagogues such as fenugreek (*Trigonella foenum-graecum L.*) have been used

for years and are well accepted in many countries, yet data demonstrating their efficacy remain elusive. Herbal preparations should be considered with caution, as these products are not standardized, may be contaminated, and may interact with prescription drugs.[65]

Analgesics for Postpartum Pain Relief

Pain following episiotomy, laceration repair, operative vaginal birth, or cesarean birth may decrease a woman's comfort and desire to breastfeed. Conversely, pain control with opioid medication may sedate a mother and newborn and decrease feeding. Nonpharmacologic methods of pain reduction, such as cold or warm packs, may be helpful in this regard.

Guidelines for use of opioids during the immediate postpartum period are presented in the *Postpartum Care* chapter.[66] If opioids are required for pain relief in the immediate postpartum period, the lowest dose possible for the shortest duration possible should be used as part of a multimodal, stepwise process to ensure optimal pain relief.[52] Although the FDA has recommended that codeine and tramadol (Ultram) not be used by breastfeeding women,[51] there are occasions when opioid medications are needed. If a breastfeeding woman requires opioids for pain control, physician consultation, a process of shared decision making, and careful documentation in the healthcare record are recommended.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are compatible with breastfeeding. Low or no amounts of ibuprofen appear in breast milk following 400 mg doses every 6 hours, making this agent an ideal postpartum pain reliever and antipyretic.

Antidepressant, Anxiolytic, and Antipsychotic Medications

The effects of antidepressants on a breastfeeding infant are not fully known. Most antidepressants appear in breast milk in low concentrations, and many can be taken safely during lactation.[57,67] The medications in this class that have an RID of 10% or higher include bupropion (Wellbutrin), diazepam (Valium), fluoxetine (Prozac), citalopram (Celexa), lithium (Lithobid), lamotrigine (Lamictal), and venlafaxine (Effexor). When a breastfeeding woman requires a medication in one of these classes, the half-life, duration of action, consequences of discontinuing the medication, and factors involved in changing from one medication to another should be taken into consideration. Consultation with obstetric or psychiatric providers is recommended.

Assessment of the Maternal–Newborn Dyad During Breastfeeding

The goal of breastfeeding assessment is to evaluate breastfeeding effectiveness and to detect problems that may lead to inadequate milk transfer or breastfeeding cessation. Although the initial breastfeeding assessment should be performed prenatally, the assessment is repeated or may be performed for the first time prior to the initial assessment of the breastfeeding session. A breastfeeding assessment is performed during evaluation of any breastfeeding concern and always includes evaluation of both the woman and the newborn (**Table 35-8**).

Table 35-8	Postnatal Breastfeeding Assessment
Breastfeeding Intention	
If the woman is planning to breastfeed, the following history is obtained.	
Assessment of the Woman	
History	
History of conditions that may adversely affect breastfeeding, including polycystic ovary syndrome, diabetes, or thyroid disorder	
History of breast surgery including mastectomy, lumpectomy, augmentation, or reduction	
Prior unsuccessful breastfeeding	
Current use of opioids	
Physical Examination of the Breast	
Breast: engorgement (yes/no); any scars or abnormalities	
Nipple type (retracted, inverted-appearing, common, flat), injury (cracks, abrasions, blisters, signs of infection)	
Nipple lesions: cracks or blisters	
Presence or absence of breast tissue in axilla and along milk lines. If present, this extra-mammary tissue may engorge during lactogenesis II and the woman can be counseled about expected findings if engorgement occurs.	
Assessment of the Newborn	
History	
Gestational age at birth	
Mode of birth: Operative assisted birth with forceps or vacuum may cause trauma such as cephalohematoma or bruising.	
Labor medications and duration of exposure	
Neonatal complications and/or interventions	
Voiding frequency, stool frequency, stool consistency	
Physical Examination	
Weight	
Head (cephalohematoma)	
Neck: range of motion or signs of discomfort with range of motion	
Mouth to rule out ankyloglossia[a] or thrush	

[a] Ankyloglossia (tongue-tie) is a condition in which the lingual frenulum is short or thick, such that the infant cannot

extend the tongue optimally. Although ankyloglossia has been associated with breastfeeding difficulties and nipple pain, studies of frenotomy have not consistently shown it is effective in improving breastfeeding duration. Routine examination of the frenulum is not necessary as part of an initial breastfeeding assessment.

Table 35-9 illustrates several types of nipples.[68] Most breast sizes, shapes, and configurations are compatible with breastfeeding; a few may pose temporary or permanent challenges. Flat or inverted nipples may be a challenge for the newborn to grasp; however, prenatal preparation techniques such as nipple rolling do not improve early breastfeeding. Regardless of shape or configuration, the important consideration is whether milk can be expressed and the baby can extract milk.

Table 35-9 Basic Types of Nipples

Type of Nipple	Before Stimulation	After Stimulation
The majority of women have what is referred to as a **common nipple**. It protrudes slightly when at rest and becomes erect and more graspable when stimulated. An infant has no trouble finding and grasping this nipple to pull in a large amount of breast tissue and stretch it to the roof of the mouth.		
The **flat nipple** has a very short shank that makes it less easy for the infant to find and grasp. In response to stimulation, slight movement inward or outward may be present, but not enough to aid the infant in finding and initially grasping the breast on center.		
An **inverted-appearing nipple** may appear inverted but becomes erect and easily graspable after stimulation.		
The **retracted nipple** is the most common type of inverted nipple. On stimulation it retracts, making attachment difficult.		
The truly **inverted nipple** is retracted both at rest and when stimulated. Such a nipple is very uncommon and more difficult for the baby to grasp.

Several breastfeeding assessment tools have been developed and tested.[69] To date, none has proved robust enough to be reliably used in clinical practice among all populations. A breastfeeding assessment of the maternal–infant breastfeeding dyad includes evaluation of five aspects of the breastfeeding session: (1) feeding cues in the infant, (2) latch-on and infant suckle, (3) transfer of milk, (4) maternal comfort, and (5) signs of infant satiety.[70]

Feeding Cues

Neonates are able to cue, suck, and swallow within a few minutes after birth (**Table 35-10**).[70] Newborns use touch, sight, smell, and hearing to locate the breast and move toward it with reflexive and deliberate motions. If these early cues go unheeded, the infant will escalate to more intense cues, which are also stress cues: hands and fists move toward the mouth, increased rooting, and whimpering and other vocalizations of distress.

Table 35-10 **Infant Feeding Cues or Prefeeding Behavior**

Feeding Cue	Timing of Cue	Description
Increasing alertness	Early	Especially rapid eye movement under closed eyelids
Rooting	Early	Turning the head, especially with searching movements of the mouth
Flexing	Early	Legs and arms
Flexed arm or closed fist	Early	May bring hand toward mouth
Sucking	Early, mid	Fist or finger
Mouthing	Early	Motions made with the lips and tongue
Fussing or restlessness	Mid	Crying or squirming
Full cry	Late	Turns red, high-pitched scream

Modified with permission from Cadwell K. Latching-on and suckling of the healthy term neonate: breastfeeding assessment. *J Midwifery Womens Health.* 2007;52(6):638-642.[70] © 2007, with permission from Wiley.

Infants are more likely to breastfeed well when in the light sleep or active alert state of consciousness. Many infants become drowsy and fall asleep while nursing. It can be difficult to rouse an infant from a deep restorative sleep state specifically for the purposes of breastfeeding. Although most parents quickly learn their infant's hunger cues, these cues can be reviewed with new parents as needed.[71]

Latch-on and Infant Suck

Deep latch onto the breast is fundamental to adequate milk transfer and maternal comfort. First, the mother should find a comfortable position for a 30-minute feeding session. Upright, semi-reclining, and fully reclining on her side are all common and comfortable positions.[72] The goal is for the infant to be close to the breast and the mother's body well supported so she can relax while breastfeeding. The infant should face the mother's breasts directly and be supported by her arms or hands.

Most infants can move to the breast and self-attach if the mother is in a semi-reclining position and the infant is lying prone on the woman's body with access to her uncovered breasts. If the angle of the infant's open mouth can be seen at all, it should be greater than 90° (usually 130–150°) with both lips flared outward. If the woman is upright, she can bring the alert infant toward her breast, watching for a wide-open gape, as shown in **Figure 35-3**.[72]

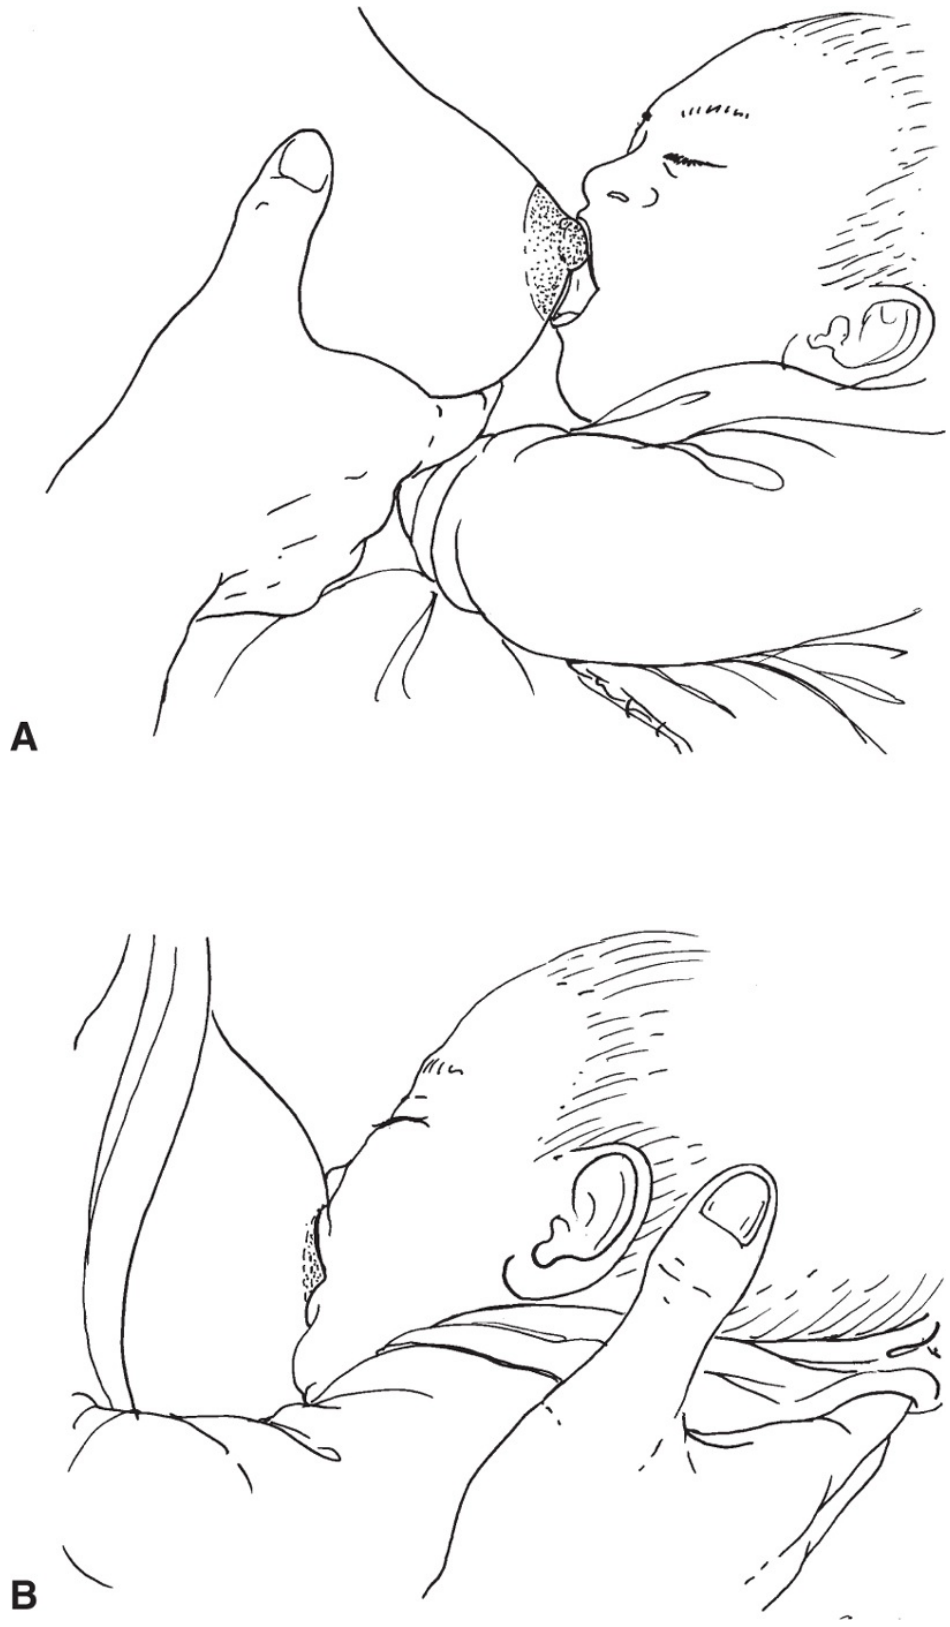

Figure 35-3 Latch-on. **A.** Mouth gaped wide open. **B.** Moving onto the breast.

Reproduced with permission from Wambach KA, Riordan J. *Breastfeeding and Human Lactation.* 5th ed. Burlington, MA: Jones & Bartlett Learning; 2016.[73]

The infant uses lips, tongue, oral cavity, jaw, facial muscles, and buccal fat pads to generate both negative and positive pressure. Positive pressure comes from the tongue moving in a

wave-like peristaltic motion, stripping the milk back toward the pharynx. Negative pressure comes from the jaw first dropping to enlarge the oral cavity and allow the milk to flow in a bolus during the let-down reflex, then rising to allow swallowing and a breath. The mother's nipple may stretch to twice its resting length inside the infant's mouth, with the tip resting near the hard–soft palate juncture.[74] The infant sucks at a rate of approximately 1.2 sucks per second.

Positions that can be used for breastfeeding are described in **Table 35-11**.[68]

Table 35-11 **Common Positions for Breastfeeding**

Position	Description	Advantages	Illustration
Cradle or Madonna position	The woman sits upright. The infant is side-lying, facing the mother; the infant nurses from the same breast as the woman's supporting arm.	Commonly used and feels natural, especially for older infants. Small infants may need more head/shoulder support.	
Cross-cradle posture	The woman sits upright. The infant is side-lying, facing the mother; the infant nurses from the opposite breast as the woman's supporting arm.	Useful for nursing a small or preterm infant; provides more stability for the infant's upper body and head.	
Football or clutch (underarm)	The woman is upright. The infant's feet are pointed toward the woman's back; the infant is supine on the woman's supporting arm or next to her body, and nurses from the same breast as the supporting arm.	Useful for women with large breasts or post-cesarean birth.	
Semi-reclining ("laid back")	The woman leans back and the infant lies prone on her chest.	Gravity helps both woman and infant. The infant can self-attach and get a deep latch, and the woman can relax without concern that the infant will fall away from her body.	
Side-lying, or "recovery" position	The woman lies on her side. The infant is side-lying facing the mother's breast. The woman's bottom arm is over or under the infant's head; the top arm is around the infant's legs or body.	The woman can fall asleep safely while the infant is nursing.	
Australian, or baby on top	The woman is "down-under," lying on her back, with the infant supported on her chest.	The infant can get a deep latch but may need head support. Useful if the woman has forceful milk ejection.	

Modified with permission International Lactation Consultant Association; Mannel R, Martens PJ, Walker M, eds. *Core Curriculum for Lactation Consultant Practice.* 3rd ed. Burlington, MA: Jones & Bartlett Learning; 2013.[68]

Assessment of Milk Transfer During Breastfeeding

Breastfeeding has a visible and audible rhythm, driven by the infant's ability to coordinate the suck, swallow, and breathe actions.[75] At the start of a feed, there is a faster suck–swallow–breathe rhythm, with the infant taking several sucks before swallowing and breathing. When the milk ejection reflex (milk "let-down") occurs, milk flows more rapidly in a bolus for

approximately 1–2 minutes and the infant responds with a 1:1:1 suck–swallow–breathe rhythm. As the flow slows, the infant reverts to more sucks before a swallow and breath. Most women experience at least two milk ejection reflexes per feeding session, even if they perceive only the first one. During the milk ejection reflex, the infant's suck–swallow–breathe pattern slows and deepens to adapt to the fast-flowing, large bolus of milk. As the milk flow slows, the infant reverts to a lighter, faster pattern with more sucks per swallow until the next milk ejection reflex occurs. The infant may stay on the breast between milk ejection reflexes and rest. The infant will release the breast comfortably when satiated.

Maternal Comfort During Breastfeeding

Physical comfort of the woman is paramount when initiating breastfeeding and implies more than a comfortable physical posture. The breastfeeding woman should have all things she may find she needs within easy reach, such as reading materials, glasses, water, or telephone. She also may find it helpful to have the aid of breastfeeding devices such as a specially designed pillow to rest the infant on during breastfeeding (although other pillows may work equally as well). Post-cesarean or operative vaginal delivery pain relief may be needed for the woman to be comfortable.

Many women will feel nipple pain or pinching during the initial breastfeeding. Pain may be caused by poor latch, nipple trauma, or infection. Engorgement gives a sensation of fullness that becomes achy and throbbing if the breast is not emptied. Emptied breasts feel soft and pain-free between feedings.

Signs of Infant Satiety

Breastfed infants feed frequently, which is normal and consistent with their physiology and the composition of human milk. Healthy infants can be fed on demand, because frequent milk removal is the most important mechanism regulating ongoing breast milk synthesis. Infants fed "on cue" usually nurse 8 to 12 times during each 24-hour period. In the first month, infants need approximately 20–24 ounces of breast milk per day, and their stomach capacity is less than 1 ounce.[76]

Some infants tend to have a pattern of paired or cluster feeds—that is, two or more feeds, with short periods of sleep or a quiet alert state between feeding cues. Gradually, over the first few weeks after birth, most infants fall into more predictable patterns. In one study, approximately 13% of infants always had paired feeds; approximately 30% fed from only one breast per feed, and the remaining 57% mixed paired and single-side feeds.[77] In the first 6 months, exclusively breastfed infants who were fed "on cue" had 11 ± 3 feeds per 24 hours, taking 76 ± 12.6 g per feed (range, 0–240 g).[77] Formula-fed infants feed slightly less frequently than breastfed infants.

Weight Gain and Elimination Patterns as Signs of Effective Breastfeeding

Weight gain, frequent voids, and stool patterns are reliable indicators of thriving infants.[78] If

there is a question or concern about effective feeding, a pre- and post-feed weight check (infant in the same clothing and diaper) on a sensitive scale can verify that milk transfer occurred based on the infant's increased weight after feeding. Breastfed infants gain an average of 4–7 ounces per week, and often alternate linear growth with weight gain.

Newborns may void only a few times in the first days after birth, before lactogenesis is established. Once breastfeeding is established, infants who are receiving sufficient nutrition will void frequently, approximately 6–8 times per day.[78] Breastfed infants may have stools after every feeding. The frequency and consistency change as breastfeeding is established. Normal newborn stool patterns are reviewed in the *Anatomy and Physiology of the Newborn* chapter.

Breastfeeding Problems

Breastfeeding rates decline the most in the first month after birth. The most common reasons women give for stopping breastfeeding are insufficient milk production, pain and difficulty with infant suckling, and lack of maternal confidence.[3,78-82] Most of these concerns can be resolved with some assistance, education, and/or support.[3] Helping women resolve breastfeeding concerns may be one of the midwifery care practices that has the largest beneficial effect on the health of women and their families.

Table 35-12 presents cues, triggers, and teaching points for the common concerns that women voice regarding breastfeeding.[81] **Table 35-13** summarizes signs and symptoms of common breast conditions reviewed in this chapter as an aid for developing a differential diagnosis.[82]

Table 35-12 Touch Points for Overcoming Obstacles to Breastfeeding Exclusivity

Time Point	Parental Concern	Main Obstacle	Provider Advice
Prenatal	"I want to breastfeed, but since I am going to work, I need to be able to formula-feed, too."	Lack of information about combining breastfeeding and working	Strongly encourage attendance at a prenatal breastfeeding class (deserves equal time to birthing class education)
		Lack of information about milk expression and access to breast pumps	Consider a longer maternity leave, if possible Prepare to simplify life during the transition to parenting
	"My husband/partner and other family members will want to help feed the baby. Won't they feel excluded if I only breastfeed?"	Family members wanting to feed the baby	Enlist father's/partner's help in supporting the nursing partner; fathers/partners can interact with their newborn by holding the baby skin-to-skin or taking the baby out while the mother sleeps After breastfeeding is well established, others can feed the baby expressed milk by bottle
	"I want to do combination feeding, or las dos cosas."	Desire for "the best of both worlds" by combination feeding	"Puro pecho," or only mother's own milk, provides greater health benefits and helps maintain an abundant milk supply
		Lack of knowledge about the importance of frequent and exclusive breastfeeding during the early postpartum weeks for establishing the mother's milk supply	If eligible, enrollment in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) offers breastfeeding mothers a substantial food package, counseling, breast pumps, and peer counselors
Birth	"My friend says it is a good idea to ask the nurses to care for my baby at night so I can get some sleep."	Unrealistic expectations for the postbirth hospital stay	Promote immediate skin-to-skin contact after birth to facilitate the initiation of breastfeeding within the first hour
		Lack of prenatal education	Teach the mother to interpret her newborn's feeding cues and breastfeed as often as baby wants; advocate for no routine formula use in the system of care
		Frequent interruptions and excessive visitors deplete new mothers' energy	Advise the mother to request help in the hospital with breastfeeding to promote task mastery
		Increased risk of formula supplements for nighttime births from 9 PM to 6 AM	Encourage continuous rooming-in, where the mother can practice being with her baby in a controlled setting and learn to latch the baby comfortably and effectively

	"The yellow milk does not look like much. A little formula won't hurt, will it?"	Belief that the small amount of colostrum is insufficient until the "milk comes in"	Explain the potency and adequacy of colostrum and the rapid increase in milk production from 36 to 96 hours postpartum
3–5 days	"Now that we are home from the hospital, the baby seems to be feeding every hour. She or he doesn't seem satisfied with breast milk alone."	Lack of knowledge about normal frequency of feedings for breastfed newborns	Explain that 8–12 feedings in 24 hours are typical and necessary to establish an abundant milk supply
		Newborns typically begin feeding more frequently the second night after birth, when the baby is at home	Provide a hand-pump or teach hand expression, so the mother can see that she has milk
		Concern about whether the newborn is getting enough milk, due to the mother's inability to see what the newborn takes at the breast	Explain normal newborn elimination patterns once the mother's milk comes in (3–5 voids and 3–4 stools per day by 3–5 days; onset of yellow, seedy milk stools by 4–5 days)
		Sleepy newborn	Perform newborn test weights (before and after feeding) to reassure the mother about baby's milk intake at a feeding Teach the mother the difference between newborn "flutter sucking" or "nibbling" that results in only a trickle of milk at the breast versus "drinking" milk, with active sucking and regular swallowing Tickling under the axilla or holding a hand up can help keep baby on task at the breast; compressing the breast when the baby stops slow, deep sucking can deliver a spray of milk to entice him or her to start drinking again Anticipate a newborn appetite spurt at approximately 10–14 days of age
	"My nipples are sore and cracked. Can I take a break and give my baby a little formula?"	Sore nipples are usually attributable to incorrect latch-on technique and are a common reason that mothers discontinue breastfeeding early or start supplements	Observe a nursing session to evaluate latch; consider referring the mother to a lactation consultant for one-on-one assistance with latch
2 weeks	"My breasts do not feel very full anymore. I'm afraid my milk went away."	As postpartum breast engorgement resolves and the breasts adjust to making and releasing milk, mothers may perceive that they have insufficient milk supply	Expect the newborn to be above birth weight by 10–14 days and reassure the mother about the newborn's rate of weight gain since the 35-day visit Although the mother's breasts are less swollen than during postpartum engorgement, they should feel fuller before feedings and softer afterward
	"How can I know my baby is getting enough?"	The days 10–14 appetite spurt can cause the mother to doubt the adequacy of her milk supply	Consider performing test weights (before and after feeding) to reassure the mother about her newborn's intake Anticipate another appetite spurt at approximately 3 weeks of age
1 month	"My baby is crying a lot, and I am tired and need sleep."	Normal infant crying peaks at approximately 6 weeks (3–5 hours in 24 hours)	Congratulate the mother on a full month of breastfeeding!
		The mother may attribute infant crying to hunger or an adverse reaction to her milk	If the infant has gained weight appropriately, reassure the mother about the adequacy of her milk supply Offer coping strategies for infant crying, including holding the baby skin-to-skin; the Five S's[a] (swaddle with the baby's hands up near the head to help assess feeding cues); use of an infant carrier; going for a stroller or car ride; observing a period of "purple crying"
	"Nothing seems to calm my baby except the bottle."	If the infant drinks milk from a bottle that is offered, the mother may assume that her infant is not satisfied by breastfeeding	Explain that infant sucking is reflexive, and drinking from an offered bottle does not always mean that the baby is hungry; a baby "can't scream and suck at the same time," so the bottle may appear to calm the baby, just as a pacifier might If the mother desires to offer a bottle, use expressed milk as the supplement Forewarn the mother about cluster feedings (late afternoon/evening) and upcoming appetite spurts, occurring at about 6 weeks and 3 months
2 months	"My mother said that, if I give my baby rice cereal in a bottle before bedtime, he or she may sleep longer at night."	Parental sleep deprivation	Explain the lack of evidence that rice cereal or other solid foods increase infant sleep

		The mother may have already returned to work, which often increases fatigue and leads to a decrease in milk supply	Remind the mother that adding complementary foods is a project and increases the workload for parents Reinforce the benefits of exclusive breastfeeding for maternal–infant health and the mother's milk supply
	"I am going back to work and am worried that I do not have enough frozen stores of milk. Are there any herbs I can take to keep my milk supply strong?"	Lack of knowledge about the principles of milk production and unrealistic beliefs about the effectiveness of galactagogues	Enlist help from others, including support for returning to work Explain that there is no "magic pill" or special tea to increase the mother's milk supply; the key to ongoing milk production is frequent, effective milk removal (every 3–4 hours) Caution the mother to avoid going long intervals without draining her breasts
4 months	"My baby seems to eat for only a few minutes, and when I try to put her/him back to the breast, she or he refuses."	Misinterpretation of infant's efficiency in nursing causes concern about infant milk intake	Explain that infants become more efficient at breastfeeding, and by 3 months, they may drain the breast in 4–7 minutes Reinforce continuing to delay the introduction of solid foods
	"My baby seems more interested in everything around him or her than in nursing at the breast."	Normal infant distractibility causes the mother to believe her infant is self-weaning	Explain that distractibility is a normal developmental behavior at this age and that short, efficient feedings are common Nurse in a quiet, darkened room
6 months	"My baby is drooling and rubbing on her or his gums all the time. I do not think that I can continue to breastfeed because my baby might bite me."	Common myth that a mother needs to wean when her baby gets teeth to avoid being bitten while breastfeeding	Congratulate the mother on 6 months of exclusive breastfeeding! Explain that infants cannot bite and actively breastfeed at the same time. Biting tends to occur if the breast is offered when the infant is not interested or at the end of the feeding If the infant bites, say "No biting," touch the infant's lips, set the baby down, and briefly leave the room
	"My baby has refused to breastfeed for almost a whole day now. Is she or he ready to wean?"	Misinterpretation of sudden breastfeeding refusal ("nursing strike") to mean that a baby is self-weaning	Explain that some infants may suddenly refuse the breast between 4 and 7 months of age for no apparent reason; common causes include upper respiratory infection, ear infection, teething, regular exposure to bottle-feeding, use of a new soap/perfume, maternal stress, or a decrease in milk supply Because many infants will nurse while asleep, try offering the breast when the baby is drowsy or asleep Regularly express milk if the baby will not nurse, and feed the pumped milk until the infant resumes breastfeeding

[a] The Five S's consist of swaddling, side-lying, swaying, shushing, and sucking. The Five S's are interventions recommended to help an infant stop crying promoted by Dr. Harvey Karp. Of note, these interventions have not been the subject of research.

Table 35-13 Signs and Symptoms Associated with Common Breast Conditions in Women Who Are Lactating

Condition	Definition	Description	Systemic Symptoms	Fever	Pain	Unilateral vs. Bilateral	Other
Engorgement	Breast is engorged	Hard, enlarged, shiny, bilateral erythema	No, occasional transient fever "milk fever" that resolves within 24–48 hours	< 38.4°C	Yes	Bilateral	Associated with onset of lactogenesis II
Blocked ducts[a]	Lump of localized milk stasis	Single lumpy area; may have erythema	Unlikely	Unlikely	Tender or localized pain	Usually unilateral	May occur with a painful white bleb on the nipple[b]
Galactocele	A milk-retention cyst	Smooth, well-demarcated mass	No	No	Maybe	Usually unilateral	Compression of the cyst may cause milky fluid to exude from the nipple
Inflammatory mastitis	Secondary to ineffective and/or obstructed drainage of milk from the breast	Erythematous	Yes, in 50–66% of women	Mild: < 37.5 °C Acute: > 37.5°C and < 38.5°C Hyperacute: > 38°C	Yes, localized	Usually unilateral	See note[c]
Infectious mastitis	Results from untreated milk stasis and/or colonization with pathogenic bacteria	Hard, may be wedged shaped; may be erythematous	No, in 33–50% of women	Mild: < 37.5 °C Acute: > 37.4°C and < 38.5°C Hyperacute: > 38°C	Usually	Usually unilateral but may be bilateral	See note[c]
Breast abscess	A localized infection that has formed a barrier of granulation tissue	Swollen mass, possibly fluctuant, with erythema	May or may not be present; may follow mastitis	May or may not be present	Usually severe	Often unilateral but may be bilateral	

[a] May be referred to as "focal breast engorgement," "caked breast," or "plugged duct."
[b] The bleb may be opened up with warm water soaks, massage, or a sterile needle.
[c] The clinician cannot reliably differentiate noninfectious mastitis clinically from infectious mastitis. Treat the woman with antibiotics if she is acutely ill, there are severe or bilateral symptoms, there are nipple fissures, or symptom resolution does not occur within 12–24 hours of improved milk removal.

Breast Engorgement

Breast engorgement is a nonspecific term that describes breast hardness and fullness that is associated with pain or discomfort. Primary engorgement occurs in most women at the onset of lactogenesis II and is believed to arise secondary to a combination of milk and interstitial edema.[12] Secondary engorgement can occur at any time if milk is not emptied from the breast. When engorgement is severe, the nipple may flatten and the infant may not be able to effectively latch onto the nipple.

Primary engorgement generally lasts approximately 48 hours and resolves spontaneously. The goals of treatment are to facilitate infant latch and decrease maternal discomfort. If the areola is involved, a small amount of milk can be expressed via hand or a breast pump to soften the areola. The breast does not need to be fully emptied. If more than two-thirds of the retained milk is removed, milk production will increase; conversely, if less than one-third of retained milk is removed, milk production will remain stable or decrease.[12] It is best to allow the infant to control the amount of milk removed from the breast.

Remedies for postpartum breast engorgement remain insufficiently tested.[83] Common treatments include wrapping the breasts tightly to facilitate comfort, ice packs, application of cold cabbage leaves, and use of analgesics such as ibuprofen. Although a popular home remedy, application of cold cabbage leaves does not appear to be more or less beneficial than application of cold packs.[84]

Delayed Lactogenesis II

Delayed lactogenesis describes a longer than expected interval before lactogenesis II occurs. Delayed lactogenesis is distinct from failed lactogenesis or secondary insufficiency of milk production. Each of these conditions is addressed in turn in this section.

The definition of delayed lactogenesis II used clinically and in many research protocols is no obvious signs of milk production 72 hours or more after birth.[85] Nevertheless, this definition may not reflect the normal variability in human physiology. Although most of the studies conducted on timing of lactogenesis II are several years old and rely on small sample sizes, some conclusions can be drawn. Neville et al. found the timing of lactogenesis in multiparous women occurs between 46 and 92 hours postpartum.[86] Arthur et al. reported women detected lactogenesis II between 38 and 92 hours postpartum, with the mean being 74 hours after birth.[87] A more recent study by Brownell et al. (n = 2491) surveyed women in the United States who gave birth to a healthy infant at 35 weeks' gestation or later. In this study, 11% of the participants experienced lactogenesis II at 1 day postpartum or sooner, 66% at 2 to 3 days postpartum, 15% at 4 days postpartum, and 8% after the fourth day postpartum.[88] In summary, the normal timing of the onset of lactogenesis II may occur later than previously believed.

Despite the lack of clear guidelines to define delayed lactogenesis II, some risk factors are well known. Primigravidas are likely to experience lactogenesis II later than multigravidas, with the range reported as approximately 24 hours.[89] Women who have cesarean births may also experience lactogenesis approximately 24 hours later than women who have vaginal births, but do not experience lower quantities of milk production.[88,89]

Delayed lactogenesis can be due to retained placental fragments, diabetes, thyroid disease, preeclampsia, pituitary tumors, Sheehan syndrome, theca-lutein cysts, polycystic ovary syndrome (PCOS), high maternal BMI, and gestational diabetes.[56,88–90] A review of medications that may reduce milk supply may be considered when a woman experiences such a delay. Recently, consuming encapsulated placenta has been suggested as a risk factor in delayed or failure of lactogenesis II.[91]

Obesity and Delayed Lactogenesis

Women with prepregnancy obesity are known to have lower breastfeeding initiation rates, delayed lactogenesis II, and shorter breastfeeding duration.[92] Many factors may contribute to lower rates of breastfeeding initiation in women with high BMIs, including increased use of Pitocin for prolonged labor and increased incidence of cesarean birth. The underlying mechanism of action may be related to higher levels of leptin in this population. Leptin, an adipokine produced in adipose tissue, is a tocolytic agent that may reduce oxytocin's action in the milk ejection reflex.

Milk expression or pumping after feedings in the early postpartum period, breast massage, and warm compresses may enhance early breastfeeding efforts for women with obesity. These women may also benefit from early breastfeeding education, lactation support visits or phone calls, and peer support groups.

Failed Lactogenesis II

Although rare, failed lactogenesis may occur secondary to mammary hypoplasia. While the incidence of mammary hypoplasia has not been studied rigorously, estimates are that fewer than 5% of women have underdeveloped mammary glandular tissue. During physical examination, breasts with insufficient mammary tissue may appear tubular, widely spaced (more than 1.5 inches between the breasts at the sternum), or markedly asymmetrical in size and shape. Breasts with insufficient mammary tissue do not grow—that is, bra cup size is unchanged—during pregnancy.[93]

Many women with mammary hypoplasia will give formula supplements following each feeding or change to exclusive formula-feeding. Women with mammary hypoplasia need reassurance and support as they determine the best choices for infant nutrition.

Insufficient Milk Supply

Women concerned about insufficient milk supply often report infant crying often and lack of fullness in the breasts. Supply and demand is the basic principle governing milk production: The emptier the breast, the faster milk is produced in the alveoli. When the breasts are emptiest, the rate of milk production is approximately 2 ounces per hour per breast. When the breasts are fullest, the rate drops to approximately

ounce per hour per breast, with an hourly average rate of 1 ounce per hour per breast.[94] Common etiologies of insufficient milk supply are not emptying the breast frequently enough and insufficient emptying by the newborn.

Assessment for insufficient milk supply includes obtaining a history of time intervals between nursing, duration of each feeding session, and use of medication that could lower milk production. The infant should be examined and weighed. Observation of a breastfeeding session can detect problems with infant latch. If the infant is nursing well, is gaining weight, and has a normal elimination pattern, insufficient milk supply is unlikely. In this case, sharing information about normal infant developmental growth spurts and expected hours of infant crying in a 24-hour period can help reframe and contextualize infant behavior. The woman can also weigh the infant before and after a feeding session to obtain data showing effective milk transfer. Manual expression or using breast pump after feeding can enhance milk production if necessary.

If the infant has lost weight or has signs of hyponatremia, consultation with a lactation consultant and/or pediatric provider is indicated.

Plugged Ducts and Galactoceles

Plugged ducts are usually attributed to restriction of milk flow in one section of the breast. Encourage women to feed their infants frequently, preferentially offering the affected breast first, to more thoroughly drain the plugged areas. Positioning the infant’s chin toward the blocked area may improve drainage. Manual massage toward the nipple may clear a plugged area. Plugged nipple pores (white bleb) on the tip of the nipple are pinpoint-tender and usually

related to a plugged duct. Gentle massage and warm water soaks will usually relieve the plug.

A galactocele is a milk retention cyst that results from a blocked duct and presents as a cystic, usually nontender mass. Galactoceles are uncommon during lactation, but rather are most likely to develop during the process of weaning. Although these cysts are benign, the differential diagnosis includes breast abscess, lipoma, fibrocystic changes, and breast malignancy. The diagnosis can be made on ultrasound and/or via aspiration. Very rarely, if the galactocele is quite large or painful, repeat aspiration or excision may be recommended.

Conditions That Affect the Nipple and Areola

Pain and dermatoses that affect the nipple and areola can appear in the first days after the infant starts breastfeeding, or they can appear later, after breastfeeding is well established.

Conditions That Appear with the Onset of Breastfeeding: Nipple Trauma

During the first 3 to 4 days of breastfeeding, nipple pain or discomfort is normal for the first 30–60 seconds of nursing. This initial pain dissipates once the infant is firmly latched and suckling effectively. Pain that persists throughout the breastfeeding session or pain that worsens over time needs further evaluation.

In such a case, the nipple should be inspected to identify cracks, abrasions, blisters, or signs of infection. The next step is to determine the etiology. Nipple pain is most commonly related to the infant's inability to effectively latch onto the nipple. If the infant latches on too close to the nipple tip, the nipple is compressed between the infant's tongue and hard palate, creating pressure and eventually friction damage. The remedy is a deeper latch that pulls the nipple farther into the infant's mouth so the nipple touches the soft palate and not the hard palate during suckling.

If there is no obvious nipple injury such as cracks or blisters and repositioning the infant does not relieve the pain, a disorganized or dysfunctional suck is the next likely cause. Immaturity, oral anatomy, and muscular tone can be factors that can be evaluated by a lactation consultant or an oral-motor specialist. Ankyloglossia can quickly inhibit effective milk intake and simultaneously damage a woman's nipples, although most infants with ankyloglossia do not have difficulties nursing. A lactation consultant and/or pediatric provider can evaluate the infant for ankyloglossia and consideration of frenotomy.

Several remedies have been proposed for treating nipple trauma that develops in the first days of breastfeeding, including anhydrous lanolin, nipple shields, and applications of breast milk. Application of breast milk to the injury and use of a breast shield to protect the area between feedings appears to be more effective than anhydrous lanolin (which must be wiped off before breastfeeding), breast shields, or glycerin gel dressings.[95,96]

Conditions That Appear After Breastfeeding Is Established

The list of differential diagnoses for women with late-onset or new-onset nipple pain after breastfeeding has been established is broad. Potential causes include (1) infection—fungal, bacterial, or, rarely, viral (herpes); (2) noninfectious nipple trauma, including eczema, atopic

dermatitis, psoriasis, vasospasm, and rarely Paget's disease of the nipple; and (3) Raynaud's syndrome.

Noninfectious Conditions of the Nipple/Areolar Complex. Noninfectious conditions such as dermatitis (atopic, irritant contact, or allergic contact) or psoriasis usually affect the areola. Acute eruptions may produce vesicles, crusting, and erosions, whereas chronic eruptions are characterized by a dry, erythematous, and scaling pattern. Women with a history of eczema may develop atopic dermatitis that starts at the nipple and spreads across the areola to the breast. Irritant contact dermatitis is the result of direct contact. Possible irritants include soaps, topical antibiotics, and new unwashed clothing. In such a case, the affected area is limited to sites on the breast that were in contact with the irritant. Allergic dermatitis is a hypersensitivity reaction to an irritant. Possible allergic irritants include lanolin, tannic acid from tea bags, vitamins A and E, aloe vera, and fragrances. Consultation with a dermatologist may be indicated.

Infectious Conditions of the Nipple/Areolar Complex: Bacterial Versus Candidal. Infections often follow or present concomitantly with injury to the skin; they may also occur secondary to bacterial or fungal colonization. Diagnosis of candidal versus bacterial infection can be challenging, as the same signs and symptoms are observed in both types of infections. Furthermore, there is controversy about obtaining results from breast milk cultures because breast milk has antibacterial properties and contains lactoferrin, which suppresses growth of *Candida albicans*. This problem has greatly hampered attempts to accurately diagnose the organism responsible for these conditions.[97]

Infection of the nipple/areolar complex is usually diagnosed on the basis of history and physical examination. Women with candidal infection may report a history of their infant having thrush or severe diaper rash, or the infant may have signs of thrush. The nipple and areola are often shiny and red, and there may be flaking of the skin around the nipple or cracks in the areola. The pain is frequently out of proportion compared to the physical findings and typically includes burning, itching, stinging, "piece of glass" feelings, or deep stabbing pain that radiates back toward the chest wall. The stabbing pain has been hypothesized to occur secondary to infection in the ductal system. Multiple symptoms have a higher predictive value than single symptoms for candidal infection, as shown in **Table 35-14**.[98,99]

Table 35-14	**Positive Predictive Value of Signs and Symptoms of *Candida* of the Breast in Lactating Women Between 2 and 9 Weeks Postpartum**
Sign/Symptom	**Positive Predictive Value**
Sore + burning + pain + stabbing + skin changes[a]	100%
Burning + pain + stabbing + skin changes	100%
Pain + stabbing + skin changes	100%

Sore + burning + pain + skin changes	80–91%
Burning + pain + skin changes	80–85%
Sore + burning + pain + stabbing	74%
Burning + pain + stabbing	63%
Pain + stabbing	57%

Most women with severe nipple/areolar pain and/or deep stabbing breast pain respond well to antibiotics or fluconazole (Diflucan), or both. If candidal infection is suspected, the infant should be simultaneously treated with a topical antifungal.[99,100] Empiric treatments often used for nipple/areolar infections are presented in **Table 35-15**.

Table 35-15 Treatment Options for Nipple and Breast Infections

Condition	Treatment
Nipple/areolar infection[a]	*If bacterial infection is suspected:* Mupirocin 2% ointment (not cream): 15 g. If no improvement, culture and treat based on sensitivity results or treat empirically for yeast or consider other etiologies. Polymyxin B sulfate (Bacitracin): Apply mupirocin or polymyxin after each nursing or pumping. *If candidal infection is suspected[b]:* Infant: Nystatin (Nilstat) 100,000 units/mL. Place 1 mL in cup, then swab the inside of the infant's mouth 4 times/day. 2 mL 4 times/day for older infants. Have the infant drink what is left. Gentian violet 1% in 10% alcohol, applied to the infant's mouth with a Q-tip before feeding, so that the mother's nipple will be coated during the feeding. It should be used daily for 4 days, although treatment duration may be extended to 7 days if there is improvement but no resolution. Mother: Topical treatment with nystatin (Nilstat) suspension. Miconazole (Monistat-derm) or clotrimazole (Lotrimin) may be preferred, as resistance to nystatin is increasing. Apply cream or suspension after each nursing. Allow suspension to air dry or, if using cream, rub in a small amount. Gentian violet 1% in 10% alcohol, applied to the nipple. It should be used daily for 4 days, although treatment duration may be extended to 7 days if there is improvement but no resolution. Anti-inflammatory cream and/or antibiotic cream to treat overgrowth with *Staphylococcus aureus*. The topical treatment (Dr. Newman's APNO) is applied sparingly after each feeding and used until nipple soreness has dissipated. APNO is compounded and contains the following ingredients: mupirocin 2% ointment (not cream): 15 g; betamethasone 0.1% ointment (not cream): 15 g; and miconazole powder to formulate a final concentration of 2% miconazole. If miconazole is unavailable, substitute clotrimazole powder added to a final concentration of 2%.
Ductal infection (deep shooting, burning pain)	If topical treatment does not resolve symptoms, systemic treatment for the mother may be considered. Some authors recommend use of fluconazole only after confirmation of candidal infection via breast milk culture or potassium hydroxide examination of skin scraping. Fluconazole (Diflucan): 400 mg loading dose, followed by 200 mg/day for 14 days. Considered safe for the breastfeeding infant.
Infectious mastitis	First-line choices: Dicloxacillin (Dynapen) 500 mg 4 times/day for 10–14 days *or*

	Cephalexin (Keflex) 500 mg 4 times/day for 10–14 days *or* If penicillin allergic, use clindamycin 300 mg 4 times/day or erythromycin 250 mg or 500 mg 4 times/day for 10–14 days Cultures of milk and nipple are indicated for maternal acute illness, failure to respond to treatment, high suspicion of MRSA, and bilateral mastitis. The infant may need to be treated for these conditions concurrently, particularly if infection with group A or B *Streptococcus* is suspected.
Recurrent mastitis	Culture and treat as appropriate for 14–30 days. Low-dose erythromycin or clindamycin may be given on a daily or weekly basis. Consider cultures and treatment with nasal mupirocin (Bactroban) if an *S. aureus* carrier state is suspected.
Ductal infections	Culture and treat as appropriate for at least 14 days. It may be prudent to treat the woman until her symptoms have been resolved for at least 1 week. Can empirically start treatment with clindamycin 300 mg 4 times/day or sulfamethoxazole–trimethoprim (Bactrim) double strength bid. Treat with antifungals if any signs of yeast infection appear in the infant. First-line: Fluconazole (Diflucan) 200–400 mg STAT, followed by 100–200 mg daily for 2–3 weeks or until symptoms have been resolved for 1 week. Ketoconazole (Nizoral) may also be used.
Breast abscess (puerperal)	Outpatient: Dicloxacillin (Dynapen): 500 mg orally 4 times/day for 10–14 days *or* Cephalexin: 500 mg 4 times/day for 10–14 days *or* If penicillin allergic: Clindamycin (Cleocin) 300–400 mg orally 4 times/day for 10–14 days *or* If risk for MRSA[c] and infant is beyond the neonatal period: Trimethoprim–sulfamethoxazole 1DS tablet orally 2 times/day or clindamycin 300 mg 3 times/day Inpatient: Nafcillin or oxacillin 2.0 g every 4 hours IV or cefazolin 1.0 g every 6 hours IV or vancomycin 1.0 g every 12 hours IV Incision and drainage, or use ultrasound-guided needle for aspiration. Send aspirate or discharge for culture. Infants may continue nursing on the affected side unless the area of incision involves the areola. May want to treat infant concurrently if the mother has *S. aureus* or streptococcal disease.

Abbreviations: APNO, All-Purpose Nipple Ointment; DS, double strength; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*.

[a] All treatments for nipple/areolar pain and/or ductal infection are empiric. There is little evidence to indicate which therapy is superior.

[b] If Candida is suspected or diagnosed, both mother and infant must be treated concurrently, even if one is asymptomatic.

[c] Risk factors for MRSA include recent hospitalization, recent surgery, hemodialysis, HIV infection, injection drug use, prior antibiotic use (failed therapy), military service, sharing sports equipment, and sharing needles or razors.

Raynaud's Phenomenon. Nipple vasospasm may be the cause of pain following breastfeeding or when the nipples are exposed to cool air, such as after a shower, in cold temperatures, or with cold air blowing from automobile air-conditioning ducts. Blanching or purple color changes with sharp, burning pain may be experienced. Connective tissue diseases or Raynaud's phenomenon may be related and should be explored.[101] Some clinicians use nifedipine (a beta blocker) for nipple spasms unrelieved by avoiding cold exposure or warmth.[102]

Mastitis

Mastitis refers to a breast inflammation such that one or more segments of the breast are hot, red, and inflamed. Risk factors for infectious mastitis include unresolved milk stasis, nipple damage, and previous episodes of mastitis. Mastitis is common, affecting as many as 1 in 5 women. Approximately 11% of women with mastitis will develop a breast abscess if the mastitis is not treated, and approximately 3% will develop an abscess even when the mastitis is treated.[103] The evaluation of a woman with symptoms of mastitis includes a breast examination to rule out breast abscess.

The diagnosis of mastitis is made clinically on the basis of a localized, unilateral area of erythema with associated fever (38.5°C [101°F] or higher) and feelings of malaise, flu-like symptoms, and fatigue. The infective agents most commonly implicated in this type of mastitis include *Staphylococcus aureus* and coagulase-negative *Staphylococcus* (CoNS), although *Candida albicans*, *Escherichia coli*, *Enterobacteriaceae*, and *Mycobacterium tuberculosis* have also been cultured from infected breasts. Bilateral mastitis, although rare, is likely to be associated with *Streptococcus* infection. Methicillin-resistant *S. aureus* (MRSA) mastitis has been noted in communities with a high prevalence of these bacteria.[104] Most symptoms resolve within 48 hours with sufficient and frequent breast emptying, adequate fluids and nutrition, and antibiotic therapy.

If symptoms do not resolve within 48 hours of initiating antibiotics, or if symptoms worsen, the milk should be cultured and consultation obtained to determine the best choice of alternative antibiotic. Rarely, persistent unresolved mastitis may be an early sign of inflammatory carcinoma.

Breast Abscess

An abscess is a localized collection of pus in the breast, formed by disintegrated cells and surrounded by an inflamed area (**Figure 35-4**). The infecting organism is most often *S. aureus*, although MRSA is increasingly being identified in such cases. The differential diagnosis includes mastitis (without abscess) and galactocele. Diagnosis is based on physical examination and confirmed via ultrasound.

Breast abscesses are treated with surgical drainage or needle aspiration to allow drainage to the exterior. Antibiotics may also be recommended. A woman who develops a breast abscess is referred for physician care but may be collaboratively managed by a midwife to help support ongoing breastfeeding.

Special Populations

There are many situations in which breastfeeding is desired but may be challenging. This section reviews care of individuals who want to breastfeed but may need additional support especially to meet the infant's nutritional needs.

Breast Reduction Surgery and Breast Augmentation

Lactation is not generally impaired in women who had a breast reduction procedure that used a pedicle technique. Conversely, breastfeeding is not likely to be possible for women who had a breast reduction procedure that involved removal of the nipple.[105] Although lactation insufficiency is common among women who had a breast augmentation, outcomes are unpredictable. Some women are able to exclusively breastfeed without difficulty.[106] All women who have undergone breast surgery should be monitored for insufficient milk production and may be best supported by a lactation consultant who has experience in this area.

Maternal–Newborn Separation Secondary to Illness

Women and newborns may be separated after birth secondary to maternal or newborn ill health. Premature newborns can have short suck cycles, weak or uncoordinated suck–swallow–breathe rhythms, small oral cavities, and respiratory conditions that inhibit breastfeeding. If a newborn cannot effectively breastfeed, the goal for the mother is to express milk approximately as often as a newborn would normally feed. Most newborns nurse approximately 8 times in a 24-hour period. Milk can be expressed via hand, manual pump, or electric pump.[107] Some hospitals have milk banks, and donor milk can be used to feed the newborn. Donors are screened for HIV-1, HIV-2, human T-cell leukemia virus 1 and 2, hepatitis B, hepatitis C, and syphilis. Low-heat processing of donor milk reduces cellular components, growth factors, and nutrients in the breast milk; therefore, banked milk for preterm infants is fortified with essential nutrients.

Many different technologies and techniques may be used to assist an individual who cannot breastfeed her infant.[108] A midwife who has additional training in lactation can be part of the healthcare team helping a family in this situation. The Resources section at the end of this chapter identifies sources that may help midwives who need to offer this specialized care if a lactation consultant or pediatric specialist is not available.

Expressing Milk for Bottle-Feeding

There are many reasons why women might need to express breast milk so their infant can receive that milk via bottle. General guidance for this situation includes knowledge about ways to effectively express milk and handle expressed milk. Pumped milk maintains its quality at room temperature for 4–6 hours in environments at 66–78°F.[109] Coolers with ice or gel packs with a temperature lower than 59°F will keep milk safely for 24 hours. Breast milk can also be

stored in a refrigerator for 3–8 days (32–39°F) and in a 4°F freezer/refrigerator combination unit for 3–4 months.[109] Breast milk can be thawed overnight in a refrigerator. Once thawed, it should not be refrozen.[109]

Adoption and Relactation

Although many case reports of relactation (resuming lactation after it had stopped) and induced lactation for an adopted infant have been published, effective techniques and success rates are not well known for these techniques. Additional support by a lactation consultant is recommended for these situations.

Nutrition for Lactating Women

Lactating women use approximately 500–700 calories more per day than do nonpregnant women, with this energy being devoted to production of approximately 750–800 mL of breast milk per day once lactation is established. The recommended daily reference intakes for lactating women for macronutrients, micronutrients, and vitamins are listed in the *Nutrition* chapter. Routine supplementation is not recommended for all women, as the increased needs specific to lactation can be easily met by consuming a healthy diet. That said, women who follow a vegetarian or vegan diet, women who have undergone bariatric surgery, and women who have malabsorption disorders may need supplementation of specific micronutrients. The micronutrients particularly needed during lactation are vitamin D, long-chain polyunsaturated fatty acids, and vitamin B_{12}.

Vitamin D levels in breast milk are constitutionally low in all women. Furthermore, typical vitamin D levels in breast milk are lower than the recommended daily intake values for exclusively breastfed infants. Hence it is recommended that all breastfed infants be given an oral supplement of vitamin D 400 IU per day.

Docosahexaenoic acid (DHA), a long-chain polyunsaturated fatty acid, is abundant in the developing brain of a fetus, newborn, and infant. These fatty acids are "essential" because they are not made by the body and must be obtained from the maternal diet. Women whose diets have higher concentrations of DHA also have higher concentrations of this fatty acid in their breast milk. Although some studies have found that DHA supplementation during breastfeeding improves infant cognition, visual acuity, and development,[110] a Cochrane meta-analysis of this body of research did not find any significant benefit in women who took DHA supplements during lactation.[111] The American Academy of Pediatrics has recommended that breastfeeding women whose diet is deficient in DHA take a supplement.[1] Sufficient DHA can be obtained by consuming two servings of fish per week. Thus, women who follow a strict vegan diet are those who are most likely to benefit from a supplement that contains DHA.

Vitamin B_{12} plays an essential role in DNA synthesis and is obtained via consumption of meat or dairy products. Vitamin B_{12} deficiency in infants is associated with developmental abnormalities and anemia. Women who have undergone bariatric surgery and those who follow a vegan or lacto-ovo vegetarian diets are advised to take supplemental vitamin B_{12} in the range of 2.8 mcg per day.[112]

Infants at high risk for allergies and atopic eczema have a decreased incidence of these conditions if they are breastfed exclusively for 4 to 6 months. There is no evidence that maternal avoidance of certain foods during pregnancy decreases the risk of allergies in infants, although some evidence does suggest that antigen avoidance in high-risk mothers during lactation may reduce atopic disease.[113]

Weight Loss During Breastfeeding

Postpartum weight retention can be an important health problem for women. The evidence on the role of breastfeeding in postpartum weight loss is mixed, probably reflecting studies' poor control for the intensity and duration of lactation. However, among high-quality studies, the

data support an association, with breastfeeding accounting for a 1-kg weight loss at one year postpartum.[114] A summary review of breastfeeding among women in developed countries found that women who were breastfeeding exclusively reached their prepregnant weight approximately 6 months earlier than women who were bottle-feeding; a slowing of weight loss was observed when lactation was stopped.[6]

Women should be counseled about ways to lose their pregnancy weight after the birth. Even lactating women can safely exercise (45 minutes per day, 4 days per week) and decrease their daily intake by 500 calories to achieve a safe weight loss of 1 pound per week with no ill effects on their infant's health.[115]

Formula-Feeding

Breast milk substitutes are available for women who choose not to feed their newborn with human milk or if breastfeeding is not possible. Breast milk substitutes based on cow's milk are commonly suggested for formula-fed infants, except those with a known allergy to cow's milk. These products are formulated either as powders that are mixed with water or as premixed liquids. Incorrectly reconstituted formula risks under-nutrition or gastrointestinal irritation of the infant; therefore, liquid, ready-to-feed products may be the best option for some families. Cow's milk–based formulas are designed to approximate human milk, with similar whey/casein protein ratios. These formulations also approximate the calorie content of human milk: 19–20 calories per fluid ounce. The usual intake for a healthy term newborn is 100–110 kCal per kilogram per day. Additives found in such formulas typically include iron, vitamin D, lutein, DHA, and arachidonic acid (ARA).

Formulas that are developed from cow's milk–based hydrolysates are the first option for infants who exhibit signs of cow's milk allergies. Hydrolysates are produced by heating cow casein and whey with enzymes that split proteins into peptide chains and free amino acids. Newly developed rice hydrolysates also show promise as a first treatment in cow's milk allergy. Soy-based formulas are second-choice options, as 10% to 15% of infants who are allergic to cow's milk also react to soy products.[116]

Infants should always be fed on cue and not be pressed to consume specific amounts of formula. They should never be fed "propped" bottles or given a bottle in the crib to hold, because doing so increases the risk of choking and aspiration.

Conclusion

Most women in the United States now initiate breastfeeding, and approximately half continue breastfeeding for at least the first 6 months. Most breastfeeding-related problems have relatively easy-to-implement solutions that are within the scope of midwifery practice. Referrals to specialized lactation assistance when needed can preserve the breastfeeding relationship. A woman or primary caregiver who chooses not to breastfeed should be supported without judgment. These women and those who cannot breastfeed can be assured that their infants will receive essential nutrition via breast milk substitute formulas.

PART VII

Newborn

LILY HSIA

Welcoming the Newborn

The moment a newborn enters the world, a lusty cry brings an instant, unconditional joy and great happiness to the family. That initial, spontaneous wail reassures the newborn's mother, father, and midwife, as well as others, that this new life has just been launched onto an uncharted journey, with immense uncertainty but also great promise. Only a few seconds or minutes after the birth, the parents already have their hopes for the baby. Everyone present at the birth can now take a deep breath and feel at ease as congratulations are extended all around.

At birth, the baby has limited functional and structural adaptability. The first hour is often called the "golden hour of life," in recognition of the fact that the newborn's intrauterine to extrauterine transition is both dramatic and critical. The midwife needs to provide a safe environment to ease the transition of the neonate, whose functional and physiologic changes in respiratory and circulatory systems, thermoregulation, and glucose metabolism must begin immediately so that that the baby can rapidly assume physiologic independent without delay (discussed in the *Anatomy and Physiology of the Newborn* chapter).

As the newborn and mother bond soon after birth, one of the important functions of the midwife is to perform an initial head-to-toe examination of the newborn in front of the family. The midwife needs to be familiar with the woman's prenatal, labor, and birth history and to note any problems such as intrauterine fetal development, perinatal, genetic, family, social, and environmental factors that may adversely affect the well-being of the newborn. This immediate systematic newborn assessment by the midwife seeks to determine whether the infant's appearance and behavior are within normal limits and, if deviation from normal is found, whether neonatal and/or pediatric consultation should be sought, along with further follow-up and evaluation of any neonatal problems as required (discussed in the *Examination of the*

Newborn and *Neonatal Care* chapters).

Midwives caring for women and newborns during the first 28 days of life must maintain currency in the basic knowledge necessary for systematic evaluation and management of neonates, including a solid grounding in the physiology of the transition from intrauterine to extrauterine life and provision of rapid and supportive care when necessary, using the reliable, validated, evidence-based practices and current standards for evaluation and management described in this text.

The midwife is privileged to serve women and families at some of the most vulnerable times in their lives. To serve competently, compassionately, and with respect, the midwife seeks to strengthen the family by providing them with advocacy, resources, trust, and understanding that enable them to have a fulfilling experience during pregnancy and birth, and that assist them in making informed choices. Benefiting from the midwife's commitment and support in the form of educational and emotional nourishment, the family can move forward freely and securely in their adaptive process as they grow and flourish.

The first few moments and hours of extrauterine life are among the most dynamic of any that occur during the entire life cycle. At birth, the newborn moves from complete dependence to physiologic independence. Some organs, such as the lungs, make rapid changes that are fully accomplished within days of birth. Other organ systems, such as the hepatic system, take longer to convert to extrauterine function. Overall, the transition to extrauterine life is an ongoing process and part of a continuum that starts with conception and extends through infancy.

Extrauterine transition can be profoundly influenced by prenatal factors as well as intrapartumevents. At each birth, the midwife considers prenatal or intrapartum factors that could cause compromise in the first extrauterine hours of newborn life. Events during conception and the prenatal period that can cause compromise include fetal growth restriction, congenital malformations, genetic disorders, prenatal infections (especially viral), chronic malnutrition, prematurity or postmaturity, maternal chronic disease (e.g., cardiac, renal, hepatic, diabetes), the residual effects of environmental or workplace teratogens, and substance use by the mother. Labor and birth events that can adversely influence extrauterine transition include prolonged labor, maternal fever, hypoxic uterine conditions, birth trauma, infection, passage of meconium, fetal blood loss, use of medications during labor, difficult or operative birth, and any condition causing excessive blood loss. Accurate risk prediction is essential for selection of the appropriate site and personnel for the birth.

The most dramatic and rapid extrauterine transitions that happen immediately after birth occur in four areas: the respiratory system, the circulatory system, thermoregulation, and glucose metabolism. These four areas of transition are interdependent—failure of one can lead to impairment of others, and all must occur successfully for neonatal transition to proceed smoothly.

Respiratory Changes

Prior to birth, the fetus receives oxygen from the maternal circulation via the placenta and umbilical vein. Lung development progresses through distinct stages during gestation.[1] Initially, the airways develop into branches, as do the pulmonary capillaries, although the two systems are separated by a mesenchyme. Terminal alveolar sacs appear during the second canalicular stage, which occurs between 16 and 24 weeks' gestation. During the third, saccular stage that occurs between approximately 28 and 36 weeks' gestation, the space between the pulmonary capillaries and the alveoli diminishes so that capillaries are in direct contact with the alveolar basement membrane. Primitive alveoli develop and become lined with two types of alveolar cells. Gas exchange occurs across the very thin type I epithelial alveolar cells. Interspersed are cuboidal-shaped type II epithelial alveolar cells that produce and store surfactant. Surfactant is the complex phospholipid that lines the alveoli and keeps them partially open during exhalation via its surface-acting properties. The alveolar period starts at 36 weeks and continues throughout childhood. During this phase, more alveoli form, creating a larger surface area for gas exchange. Approximately one-third of the 300 million alveoli are mature at birth; the rest mature after birth.

The primary events that occur in the lung after birth are (1) clearance of alveolar fluid, (2) lung expansion, and (3) circulatory changes that increase pulmonary perfusion. Prior to labor, the lungs are full of fluid, which is secreted in Type II alveolar cells into the alveolar space as a secondary effect of chloride ion secretion. The term fetus begins to experience a decrease in lung fluid in the days before labor, which in turn reduces the amount of fluid that needs to be cleared during the neonate's initial respirations. Clearance of alveolar fluid is facilitated by increased production and activity of epithelial sodium channels (ENaCs). When the ENaCs become active, sodium (Na^+) ions enter the cell from the fetal lung fluid and are actively extruded from the cell into the interstitial space. This process creates an electrochemical gradient that lung fluid and chloride (Cl^-) ions follow, which results in clearing the alveoli of lung fluid (**Figure 36-1**).[2-5] During labor, fetal plasma levels of catecholamines and cortisol increase; these hormones further stimulate reabsorption of lung fluid during labor by up-regulating the genes that produce ENaCs.[3,6] This overall process causes the lungs to change from active fluid secretion to active fluid absorption.[7] Activation of ENaCs is correlated with gestational age. Preterm and near-term infants have less activation of ENaCs after birth and more lung fluid compared to term newborns, which increases the incidence of respiratory distress in these neonates.[2,3]

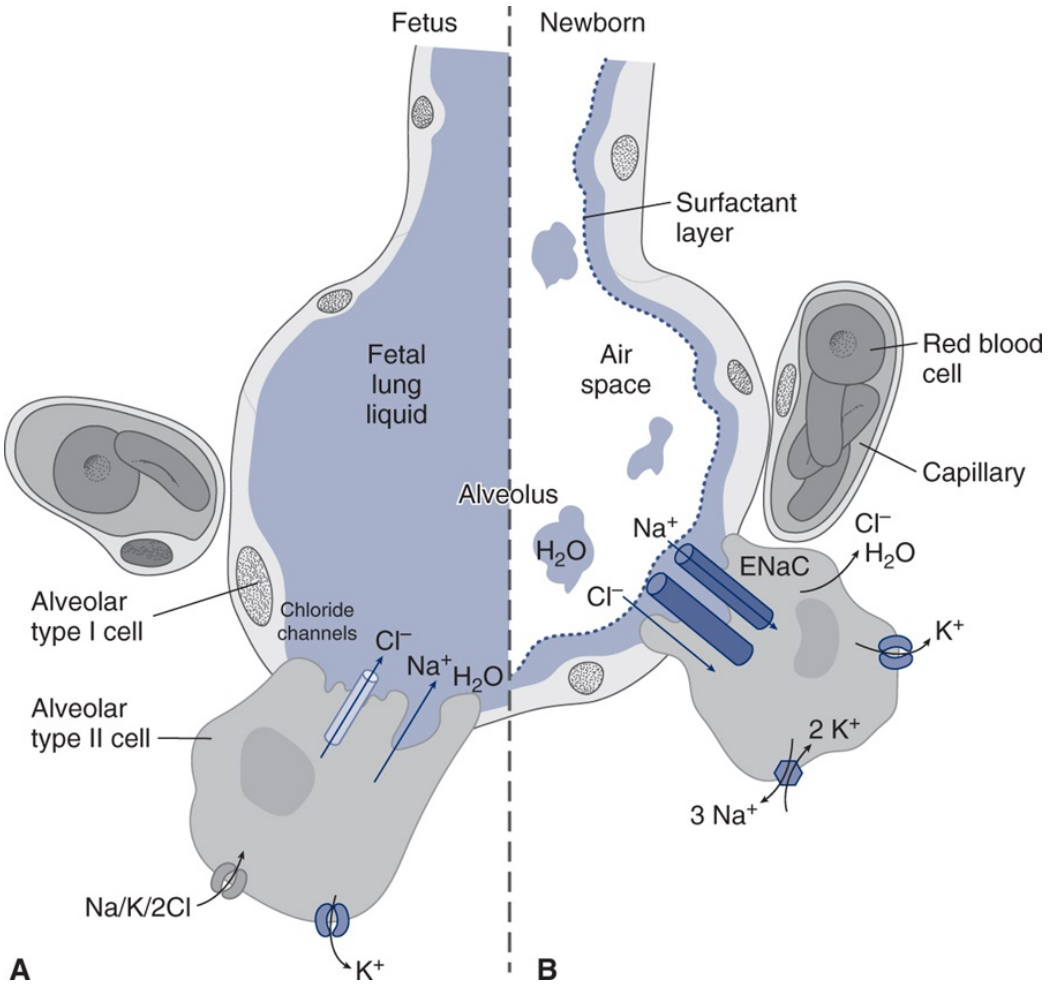

Figure 36-1 A. Fetal alveoli: Cl^- is actively excreted by the type II alveolar cell. NA^+ and water follow passively thereby secreting fluid into the alveolar space. **B.** Newborn alveoli: Epithelial sodium channels (ENaCs) upregulate in the apical surface of the alveolar cell. Na^+ enters the cell through the ENaCs. The increase in cell Na stimulates Na, K^+-ATPase activity on the basolateral aspect of the cell membrane, which drives out 3 Na^+ ions in exchange for 2 K^+ ions. When the net ion movement is from the apical surface to the interstitium an osmotic gradient is created, directing water in the same direction via either aquaporins or diffusion. This process empties the alveolar fluid into the interstitial space and pulmonary circulation.

Abbreviations: CL^-, chloride; ENaCs, epithelial sodium channels; H_2O, water; K^+, potassium, Na^+, sodium.

Based on Keene SD, Bland RD, Jain L. Lung fluid balance in developing lungs and its role in neonatal transition. In: Oh W, Guinard J-P, Baumgart S, eds. *Nephrology and Fluid/Electrolyte Physiology: Neonatology Questions and Controversies.* 2nd ed. Philadelphia, PA: Saunders Elsevier; 2012:221-232.[4]

The squeezing of the thorax that occurs in the last minutes of second-stage labor when the fetus is in the birth canal helps extrude some upper airway fluid, although this effect is small.[6,7] Neonates who experience a cesarean section birth, especially in the absence of labor, do not experience all the processes that contribute to diminution of lung fluid and have an increased risk for transient tachypnea of the newborn (TTN) or respiratory distress syndrome (RDS).

Despite decades of investigation, the phenomena that stimulate the neonate to take the first breath are only partially understood. Several biochemical and mechanical events have been

implicated in the processes. For example, the relative hypoxia of the end of labor and physical stimuli to which the neonate is subjected, such as cold, gravity, pain, light, and noise, cause excitation of the respiratory center. The release of the thoracic pressure and rebound chest expansion at birth may help stimulate a breath. With the neonate's first breath, fluid filling the mouth and trachea is partially released, and air begins to fill the tracheal column. The first active breaths set in motion a seamless chain of events that (1) assists with the conversion from fetal to adult circulation, (2) further empties the lungs of liquid, (3) establishes neonatal lung volume and the characteristics of pulmonary function in the newly born infant, and (4) decreases pulmonary artery pressure.

When the head is born, mucus drains from the nares and mouth. Many newborns gasp and even cry at this time. With the first few breaths, room air starts to fill the large airways of the neonate's trachea and bronchi. Fetal lung fluid remaining in the alveoli is pushed to the lung periphery, where it is absorbed. The first few breaths require positive pressure because room air is flowing into a fluid-filled space.[8] Newborns who are exhausted and compromised by the birth process may need assistance in clearing the fluid and mucus from the upper airway. Use of a suctioning device such as a bulb syringe or wall suction should be limited to situations in which the newborn's respiratory efforts are diminished.[9]

All of the alveoli expand with air over time. The maximum function of the alveoli occurs in the presence of adequate surfactant and adequate blood flow through the pulmonary microcirculation. After 34 weeks' gestation, sufficient quantities of surfactant help to stabilize the walls of the alveoli so that they do not collapse onto themselves at the end of each breath taken by the newborn. This surfactant effect reduces the pressure needed to expand the alveoli during subsequent breaths, thereby decreasing the workload of breathing. Adequate oxygenation is a critical factor in *maintenance* of adequate air exchange. In the presence of hypoxia, the pulmonary vasculature vasoconstricts and oxygen in the alveoli cannot be transported into blood vessels for oxygenation of other areas of the body.

If the first breaths are of adequate volume and pressure, they establish the functional residual capacity (FRC) of the neonate—that is, the gas volume left in the lungs at the end of each expiration. Crying has been found to have a functional purpose.[10] In a crying neonate, expiration is slowed by resistance from the narrowed glottis, which helps maintain end-expiratory pressure within the lungs. The muscles of the diaphragm also slow the rate of lung deflation. Control of expiration ensures a slower lung deflation that minimizes the chance of alveolar collapse and loss of the FRC.[11]

Continuation of breathing occurs secondary to central brain stem activity and the actions of specialized cells within the carotid body. In the term newborn, the chemoreceptors in the carotid body initiate increases in ventilatory effort in response to acidosis and hypercapnia, and decreases in ventilatory effort in response to hypocapnia. Respirations fluctuate—they are not stable and rhythmic for any extended period of time in the neonate. Breathing in a newborn may sound noisy and wet during this period of transition. Additionally, a newborn often experiences short periods of apnea or sighing.[12] Lack of persistent rhythm and occasional periodic breathing (irregular rhythm with short periods of apnea) are normal and more common in a near-term preterm newborn.

There are, however, certain abnormal responses to look for in the newborn. A respiratory

rate consistently faster than 60 breaths per minute, with or without nasal flaring, grunting, or chest retractions associated with breaths, is clearly abnormal at 2 hours of life. Flaring, grunting, and retracting are classic signs of respiratory distress and warrant prompt evaluation by a pediatric healthcare provider. Significant episodes of periodic breathing signal the need for medical intervention before major apnea occurs. Other normal and abnormal responses are summarized in **Table 36-1**.

Table 36-1 **Normal and Abnormal Respiratory Characteristics in the Newborn**

Characteristic	Normal	Abnormal
Respiratory rate	40–60 breaths/minute	< 30 breaths/minute or > 60 breaths/minute
Diaphragm	Diaphragmatic and abdominal breathing	Grunting with expiration
Nasal	Obligate nasal breather	Nasal flaring with breaths
Chest	No retractions	Visible suprasternal or subcostal retraction with breaths

When a newborn needs resuscitation and respiratory support, room air—rather than 100% oxygen—should be used initially.[13] The switch to 100% oxygen should be made only if room air is not sufficient. Although historically 100% oxygen has been used for respiratory resuscitation, it is now known that 100% oxygen can create free oxygen radicals that exacerbate reperfusion injury and decrease cerebral perfusion. Therefore, room air is preferred.

Circulatory Changes

The blood flow from the placenta stops with the clamping of the umbilical cord. This action eliminates the maternal supply of oxygen to the newborn and triggers a subsequent series of reactions. These reactions are complemented by those occurring in the lungs in response to the first breath.

Fetal circulation is characterized by three shunts: (1) the foramen ovale, (2) the ductus arteriosus, and (3) the ductus venosus (**Figure 36-2**). Because the lungs are a closed, fluid-filled organ, they need minimal blood flow; therefore, the pulmonary circulation has a high vascular resistance. Oxygenated blood bypasses the lungs by flowing through the opening between the right and left atria—that is, the foramen ovale—and then into the descending aorta. In the second shunt, blood in the right ventricle does not preferentially flow very far into the pulmonary arteries because of the high-pressure pulmonary vasculature, but rather flows through the ductus arteriosus directly into the descending aorta. Placental prostaglandin, prostacyclin, and low oxygen tension keep the ductus arteriosus open.[14] The third fetal shunt, the ductus venosus, connects the umbilical vein to the inferior vena cava, which allows a portion of fetal blood to bypass the circulation through the liver.

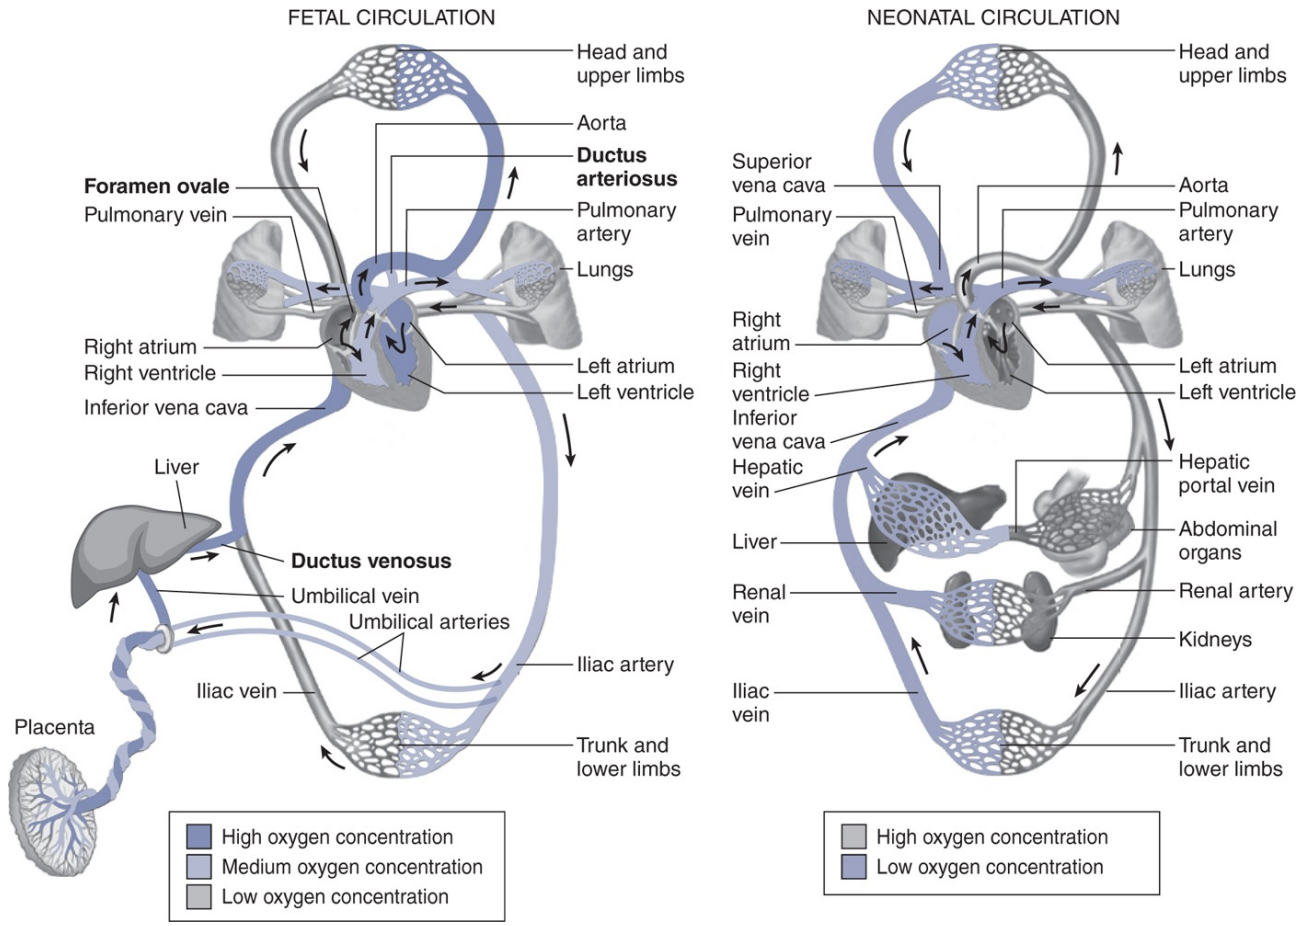

Figure 36-2 Fetal and neonatal circulation.

At birth, oxygen tension rises, and placental prostaglandins and prostacyclin no longer enter the system via the umbilical vein. This causes constriction of the ductus arteriosus. Blood from

the right ventricle is then able to enter the pulmonary circulation, and the oxygenated blood now routinely passing by the ductus arteriosus also facilitates closure of this shunt. Within 48 hours, the ductus arteriosus functionally closes.

Clamping the umbilical cord shuts down the low-pressure system that characterizes the fetal– placental circulatory unit, so that the newborn circulatory system becomes a freestanding, closed system. The immediate effect of cord-clamping is a rise in systemic vascular resistance (SVR). Most importantly, this rise occurs at the same time the newborn takes the initial breaths. The oxygen in those breaths causes the pulmonary vasculature to relax and open. The pulmonary vasculature resistance (PVR) decreases just as the SVR increases, and this shift in pressure, in combination with closure of the ductus arteriosus, encourages blood flow into the pulmonary system. A transitional period ensues during which kinked pulmonary vessels straighten which decreases resistance to blood flow. Over time, the development of elongated and thinner cell walls also increases vessel flexibility.[15]

The combination of increased SVR and lower PVR also changes the pressure of blood flow within the heart. As blood flow increases in the left side of the heart, the foramen ovale closes. The results of the change in SVR and PVR and the closure of the three fetal shunts complete the radical changes in the anatomy and physiology of the heart. Deoxygenated blood enters the neonatal heart, becomes fully oxygenated in the lungs, and is distributed to all other body tissues.

Clinical evidence of these tremendous changes in circulation is manifested as increasingly pink color, normal heart rate, and strong pulses. Although these changes are not anatomically complete for weeks, the functional closure of the foramen ovale and the ductus arteriosus occurs soon after birth. The change from fetal to newborn circulation is intimately related to adequate respiratory function and oxygenation. The term newborn who is stressed by hypoxia, hypoglycemia, cold, or infection may not make the transition smoothly and can develop persistent pulmonary hypertension.[6]

Thermoregulation

The newborn can become rapidly stressed by changes in environmental temperature. The fetal temperature is typically 0.6°C higher than the maternal temperature. Factors that contribute to heat loss in the newborn include the large surface area of a newborn (the ratio of surface area to body weight ratio in a neonate is two times higher than that of an adult), limited subcutaneous fat insulation, and a limited ability to generate heat via shivering.

Prevention of Hypothermia

Newborns can lose heat through four mechanisms: (1) convection, (2) conduction, (3) radiation, and (4) evaporation. Skin-to-skin contact between the neonate and mother is recommended as the initial method for maintaining neonatal body temperature for healthy term infants.[16] Skin-to-skin contact minimizes heat loss via conduction and results in better short-term temperature stability than bundling or placing the neonate under a warmer. This approach should be the first line of treatment for hypothermia, especially in low-resource environments.[17,18]

Coping with Cold Stress

The neonate can create heat in three ways: voluntary muscle activity, shivering, and nonshivering thermogenesis. Muscle activity can generate heat but is of limited benefit in increasing temperature, even in term infants with sufficient muscle strength. Shivering in term neonates is seen only in the most severe cold stress.

Nonshivering thermogenesis refers to utilization of brown fat for heat production. Brown adipose tissue contains more lipids, mitochondria, and capillaries than does white adipose tissue. The primary purpose of brown adipose tissue is to generate heat; such tissue is a nonrenewable resource of the newborn. Brown adipose tissue is located in and around the upper spine, the clavicles and sternum, the kidneys, and major blood vessels. The amount of brown adipose tissue depends on gestational age and is relatively sparse in growth-restricted newborns and preterm infants.

Creation of heat through utilization of brown adipose stores starts at birth, with a surge of catecholamines and withdrawal of the placental suppressors prostaglandin and adenosine. The cold stimulus of leaving the mother's warm body triggers activity in the newborn's hypothalamus that leads to oxidation of stored lipids in brown adipose and subsequent production of heat.[19] Through the mediation of glucose and glycogen, the brown adipose cells convert multiple small intracellular fat vacuoles into heat energy. The heat produced warms the blood before it circulates to peripheral areas of the neonate's body and ensures a stable temperature for other biochemical reactions.[20] In a newborn experiencing hypoglycemia or thyroid dysfunction, however, the use of brown adipose stores does not proceed efficiently.

The sequelae of heat loss in the neonate can cascade quickly into hypoglycemia, hypoxia, acidosis, and respiratory distress (**Figure 36-3**). Pulmonary vasoconstriction occurs during hypothermia, which then causes respiratory distress. These adverse effects are also

consequences of the increased metabolic demands that result from the newborn's attempts to create a neutral thermal zone.

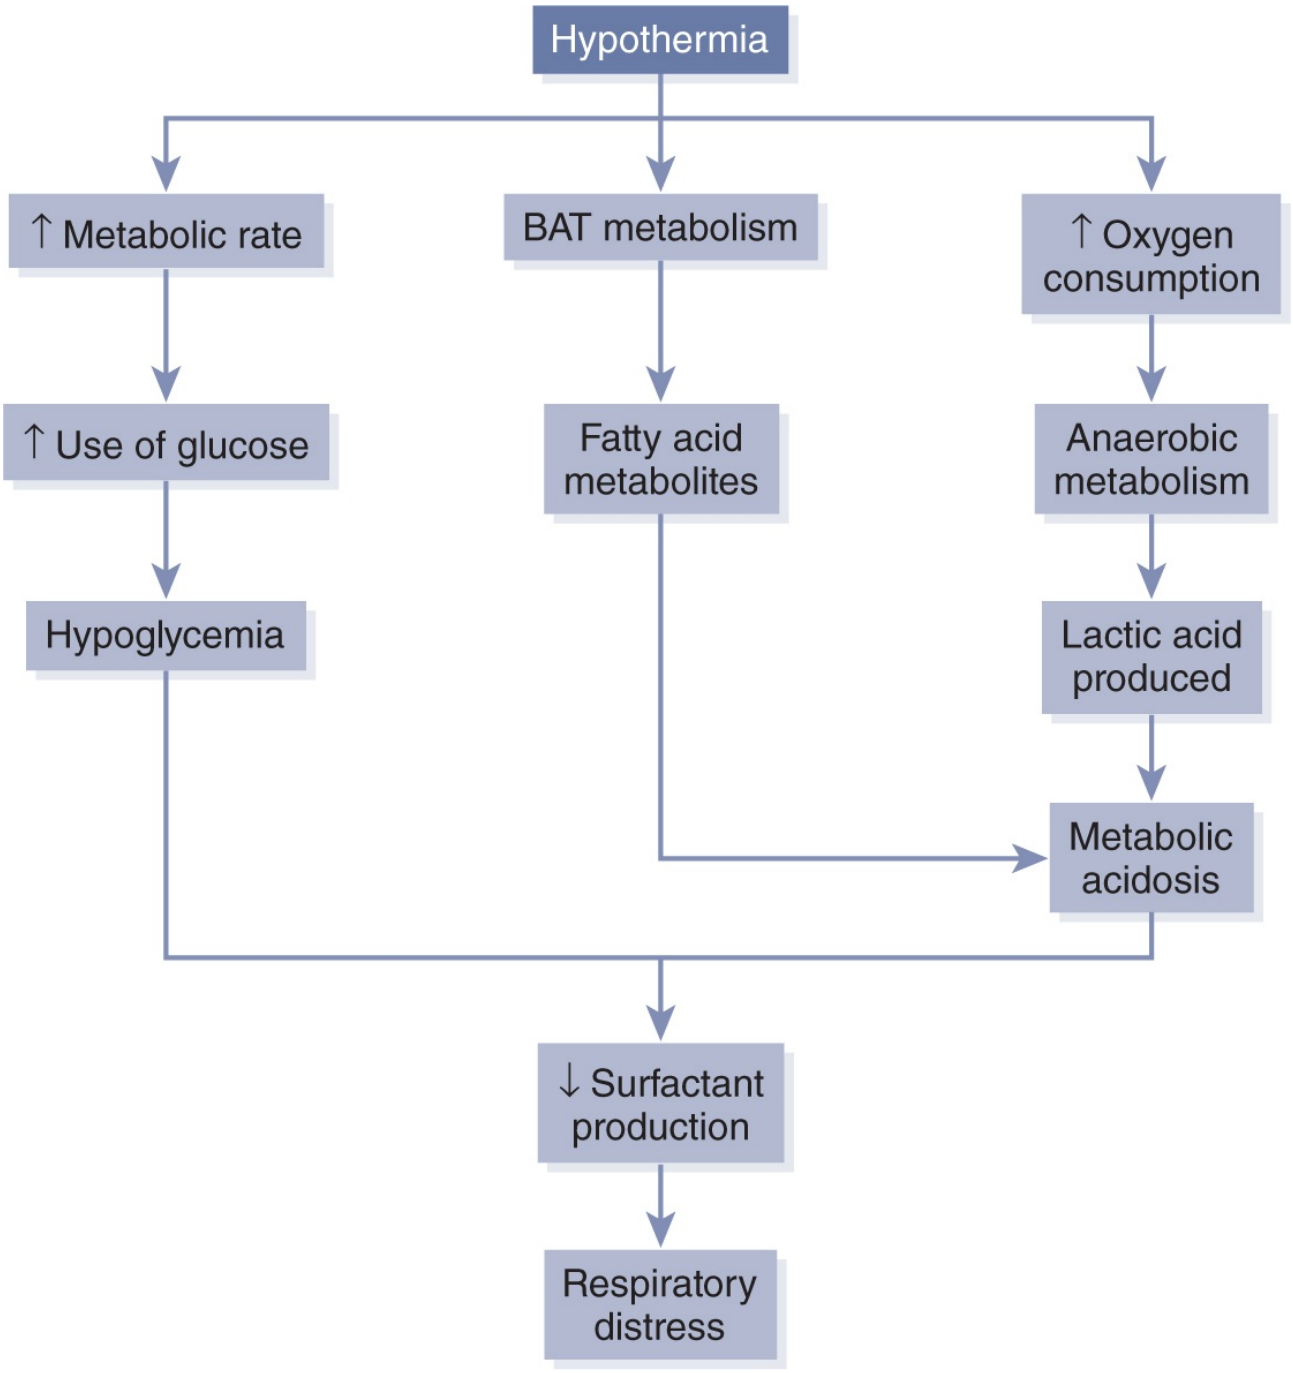

Figure 36-3 Hypothermia in the newborn.

Abbreviation: BAT, brown adipose tissue.

The World Health Organization defines hypothermia as a core temperature less than 36.5°C (97.7°F). Clinical symptoms of hypothermia may be subtle and include a low core temperature and cold skin, pale skin, pallor, hypotonia, lethargy or irritability, poor feeding or vomiting tachypnea, and an increased heart rate.[17] Any newborn who is hypothermic should be evaluated for hypoglycemia because of the high caloric demands associated with nonshivering thermogenesis.[21]

Glucose Regulation

Prior to birth, the fetus is exposed to a nearly constant blood glucose supply; the levels of glucose in fetal blood are approximately 60% to 70% of the maternal levels. In preparation for extrauterine life, the healthy fetus stores glucose as glycogen, especially in the liver. Most glycogen storage occurs in the third trimester. Although any infant can develop symptomatic or asymptomatic hypoglycemia, newborns who are growth restricted, preterm infants, post-term infants, and newborns who have experienced some form of distress prior to birth are at particular risk for hypoglycemia in the newborn period.[22] In all of these neonates, glycogen stores may be smaller than in normal term newborns. The large for gestational age (LGA) neonate is also at risk for hypoglycemia due to a different mechanism which involves increased calorie consumption to maintain body temperature. This occurs in LGA infants whether or not the mother has diabetes, with the newborn's risk increasing as birth weight increases.[23]

The moment the cord stops pulsating or is clamped, the newborn must find a way to maintain a serum glucose level sufficient for normal neonatal brain function. Blood glucose levels initially fall to a nadir at approximately 1 to 2 hours after birth. The physiologic low occurs at approximately 1 to 1.5 hours after birth, with levels subsequently stabilizing at 3 to 4 hours. In a meta-analysis of term newborns, Alkalay et al. recommended that low thresholds for plasma glucose levels in full-term newborns be designated as 28 mg/dL at 1 to 2 hours, 40 mg/dL at 3 to 23 hours, 41 mg/dL at 24 to 47 hours, and 48 mg/dL at 48 to 72 hours.[24] Their analysis included newborns fed via both bottle and breast. These researchers also noted that further study is needed to determine normal blood glucose levels for exclusively breastfed newborns.

The healthy newborn maintains blood glucose levels in one of three ways and generates glucose in the amount of approximately 4 to 8 mg/kg/minute: (1) utilization of breast milk or a substitute; (2) utilization of the glycogen stores (glycogenolysis); or (3) creation of glucose (gluconeogenesis). The newborn should be encouraged to feed as soon as possible after birth. Many newborns are active feeders during the first period of reactivity. This is an ideal time to imprint the infant with the physiologic tasks of breastfeeding. Newborns who are exhausted or stressed from long labor may show minimal interest in feeding and are therefore at increased risk for hypoglycemia.

Newborns who cannot ingest adequate nutrients will create glucose from glycogen. However, glycogenolysis can occur only if the infant has adequate stores of glycogen. Although it is possible for the newborn to create glucose from fats or proteins, the process of gluconeogenesis is inefficient and creates many metabolic by-products.

Routine blood glucose testing of term newborns after an uncomplicated birth is not recommended.[25,26] Nevertheless, all newborns should be monitored for signs of hypoglycemia. Hypoglycemia may be asymptomatic at first. Symptoms, when they occur, can be vague and nonspecific and include jitteriness, cyanosis, apnea, weak cry, lethargy, limpness, and refusal to feed. Long-term sequelae of persistent hypoglycemia include damage to the occipital area of the brain manifesting as seizures, intellectual disability, and attention-deficit disorder.[27] Damage is exacerbated when the hypoglycemia is accompanied by neonatal asphyxia.

Hematologic System

Normal values for a term newborn's blood components are listed in **Table 36-2**. Newborn blood cell indices vary by weeks of gestation, vaginal and cesarean birth without labor, and sex of the newborn.[28,29] At birth, newborns have higher values for hemoglobin and hematocrit compared to adult values. Neonatal blood contains both fetal hemoglobin (HbF), which contains two alpha subunits and two gamma subunits, and adult hemoglobin (HbA), which contains two alpha subunits and two beta subunits. HbF has a higher affinity for oxygen than does HbA, is more stable in an acidic environment, and has a shorter lifespan. After birth, HbA gradually replaces HbF. Because HbF breaks down faster than erythropoiesis, however, newborns experience a physiologic anemia approximately 6 to 8 weeks after birth. The hemoglobin level decreases slowly over the first 7 to 9 weeks after birth, reaching an average of 12.0 g/dL in a 2-month-old infant.

Table 36-2 **Hematologic Values of a Full-Term Newborn**

Component	Optimal Range
Hemoglobin concentration	14.0–20.0 g/dL
RBC count	4,200,000–5,800,000/mm^3
Hematocrit	43–63%
Mean cell diameter	8.0–8.3 µm
MCV	100–120 $µm^3$
MCH	32–40 pg
MCHC	30–34%
Reticulocyte count	3–7%
Nucleated red blood cell count	200–600/mm^3
White blood cell count	10,000–30,000/mm^3
Granulocytes	40–80%
Lymphocytes	20–40%
Monocytes	3–10%
Platelet count	150,000–350,000/mm^3
Serum iron concentration	125–225 mcg/dL
Total iron-binding capacity	150–350 mcg/dL

Abbreviations: MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell.

Based on Henry E, Christensen R. Reference intervals in neonatal hematology. *Clin Perinatol.* 2015;42:483-497[28]; Christensen RD, Henry E, Jopling J, Wiedmeier SE. The CBC: reference ranges for neonates. *Semin Perinatol.* 2009;33:3-11.[29]

Delayed Cord-Clamping

The initial hemoglobin/hematocrit values in a newborn can be influenced by the timing of clamping of the cord and the newborn's position immediately after birth. Delay in clamping the umbilical cord after birth allows a passive placental transfusion, which increases the neonate's blood volume.[30] The physiology of delayed cord-clamping is reviewed in the *Umbilical Cord-Clamping at Birth* appendix in the *Second Stage of Labor and Birth* chapter. The placental transfusion can continue for several minutes after birth to deliver approximately 30% more blood volume and 50% more iron-rich blood cells compared to immediate clamping.[30] Delaying cord-clamping has several benefits: (1) The neonate receives a bolus of oxygenated blood during the first breaths, (2) the volume expansion promotes pulmonary capillary perfusion in the newborn, (3) the more rapid achievement of adequate oxygenation leads to closure of fetal structures such as the ductus arteriosus, and (4) the infant has a decreased risk of iron-deficiency anemia at 4 to 6 months of life.[30-33] Delaying cord-clamping until cord pulsation ceases has been shown to be safe and is recommended to increase neonatal iron storage at birth despite being associated with a slightly increased risk for hyperbilirubinemia.[34,35]

To support the physiologic transfusion that occurs over the first minutes of life, the newborn is placed on the mother's abdomen (skin-to-skin) with the cord intact. This position promotes modest amounts of blood flow to the newborn without the potential danger of a forced and large bolus of blood. By 5 minutes, most of the blood flow from the cord to the neonate is usually accomplished.

Red Blood Cells and Hyperbilirubinemia

The newborn's red blood cells (RBCs) have a short lifespan of 80 days on average, compared to the adult RBC lifespan, which averages 120 days. This rapid cell turnover creates more by-products of cell breakdown that must be metabolized, including bilirubin. Newborns also have a reduction in the activity of the protein uridine diphosphate glucuronosyltransferase (UGT), which helps to conjugate bilirubin and prepare it for excretion. These two factors are most responsible for the physiologic jaundice seen in many newborns.[36] Total serum bilirubin peaks at the approximately 3 days of postnatal life. Ninety-six percent of term newborns will have a total serum bilirubin of less than 17 mg/dL at 96 hours of age, so levels higher than this concentration are considered pathological.[36] Significant jaundice before post-natal day 3 may be pathological, and any visible jaundice in the first 24 hours of life is of significant concern. There is a correspondingly high reticulocyte count in newborns, reflecting the high rate of formation of new red blood cells.

White Blood Cells

The average white blood cell (WBC) levels in a newborn range from 10,000 to 26,000/mm^3. There can be a further elevation in the WBC count in a normal newborn during the first 24 hours of life, with this level then gradually decreasing over the next 3 to 5 days. Because of these physiologic shifts, it is more useful to focus on neutrophils as a marker for infection. Limits for normal neutrophil shifts in term newborns have recently been changed to reflect a

normal peak of 28,500/mm^3 at 8 hours of age and 13,000/mm^3 at 72 hours.[37] Labor, meconium aspiration, prolonged periods of crying, and maternal fever can cause a shift upward in the neutrophil count.

Platelets and Clotting Factors

Platelet counts in newborns should be within the same range as adult values. Levels lower than 150,000/mm^3 should prompt further medical evaluation. However, platelet aggregation can vary in term newborns. In the first month of life, there is an overall deficiency of many of the clotting factors that are dependent on vitamin K. Because of this general deficiency, it is customary to give newborns supplementary vitamin K after birth. The most common route of administration for vitamin K is intramuscular, as studies have not demonstrated a reliably effective oral vitamin K dose.[38,39] Prothrombin time, thrombin time, and partial thromboplastin time are slightly prolonged.

The Newborn Immune System

The neonatal immune system is immature in a number of ways, including having incomplete physical and chemical barriers in the gastrointestinal system, limited and delayed secretory immunoglobulin A (IgA) production, incomplete complement cascade function, and decreased anti-inflammatory mechanisms within the respiratory and gastrointestinal (GI) tract. This functional immaturity renders the neonate vulnerable to many infections and allergic responses. Innate immunity is the primary line of defense for the neonate.[40]

Innate Immunity

Innate immunity consists of cellular and noncellular first responders to infection. Some examples of innate immunity include (1) the barrier protection offered by the skin, mucous membranes, and intestinal mucosa; (2) the sieve-like action of the respiratory passages; (3) the colonization of skin and intestine by protective microbes; (4) the chemical protection offered by the acidic environment of the stomach; and (5) the actions of breast milk that support neonatal innate immune function.

Skin and mucous membranes are colonized as the fetus passes through the vaginal canal. The vernix caseosa contains antimicrobial proteins and peptides (APPs) and forms a "microbial shield" on the newborn's body.[41,42] The presence of vernix also moistens the skin and increases its acidity, which inhibits growth of pathogenic bacteria.[43] The inflammatory skin reaction of normal newborns called erythema toxicum or "newborn rash" contains the antimicrobial peptide LL-37, indicating that this skin condition may be a manifestation of bacterial colonization.[40,42,44]

Colostrum that is ingested in the first few days of life and breastfeeding in the first month of life are powerful stimulants of the infant's innate immune response. Breast milk contains many bioactive substances that facilitate development of the infant's immune system. In the infant's gastrointestinal tract, breast milk inhibits binding of many toxins, inhibits inflammatory responses, and facilitates colonization of commensal bacteria that will make up the microbiome.[44] Breast milk influences expression of immune signaling genes in intestinal epithelial cells. These toll-like receptors (TLRs) play a central role in immune signaling by recognizing patterns of pathogen-associated molecular signals.[44]

Innate immunity is also provided at the cellular level. Three cell types—polymorphonuclear neutrophils (PMNs), monocytes, and macrophages—act via phagocytosis to engulf and kill foreign antigens. The PMNs will eventually become the primary phagocytes in the defense of the host. However, in the neonate, the PMN is compromised both in ability to mobilize, move in the right direction, and adhere to inflammatory sites.[42,45] These deficiencies do not reflect inadequate numbers of the PMN cells, but rather inadequate chemotaxis and opsonization.

Chemotaxis refers to the organized movement of a phagocytic cell—that is, its actual travel around the body. Opsonization is the alteration, or "marking," of the cell surface of a foreign microbe or antigen; it promotes the destruction of foreign cells. The immaturity of chemotaxis and opsonization in the newborn decreases the effectiveness of the phagocytic response and leads to one of the main weaknesses of the neonatal immune system: the inability to localize

infection. Thus, the risk for systemic infection is higher in newborns than in older children and adults.

The innate immune system also includes numerous noncellular proteins, such as complement molecules, acute-phase reactants, cytokines, chemokines, coagulation proteins, and vasoactive substances. The process of phagocytosis is enhanced if the foreign cells are prepared by complement components. Natural killer (NK) cells contribute to innate immunity, but their function is compromised in the neonate, as they have limited cytolytic ability.[46]

Signs of infection can be subtle in the newborn; changes in activity, tone, color, or feeding, for example, may be difficult to recognize in the early stages of an infection. In addition, lack of fever does not exclude the possibility of infection. Thus, observation for symptoms of systemic infection is one of the most important reasons for healthcare professional assessments of the newborn.

Adaptive Immunity

Adaptive immunity is the acquired response to specific pathogens. It is divided into two components: cellular and antibody mediated (humoral). The cellular adaptive immune response is modulated through T-cell and B-cell lymphocytes. T cells have two main roles: killing infected cells and aiding other cells by stimulation of cytokines. These cells are found in high levels in the newborn, but are slow to respond and require increased stimulus to generate their activity compared to later in life.[45] The T cells that develop immunological memory—that is, CD8 and CD4 cells—are present in low levels in the neonate; their populations increase slowly throughout childhood. Until the newborn has been exposed to some antigens, these T cells do not offer significant protection. Thus, it is not until 4 to 6 weeks after birth that the infant will experience minimal protection through the activity of these cells.[47]

The activation of the antibody-mediated B cells is dependent on T-cell activity. Thus, as a consequence of diminished T-cell functionality in the newborn, B-cell responses are also deficient, having a delayed onset and shorter duration. Bacteria may also trigger B-cell development. Recent evidence indicates that B cells are activated by maternal intestinal bacteria during early newborn intestinal colonization.

Passive Immunity

The neonate is born with passive immunity to viruses and bacteria via transplacental passage of immunoglobulin G (IgG) from the mother. Antibodies passed transplacentally to the fetus during the last trimester of pregnancy continue to protect the infant for the first few months after birth.[45] The newborn is dependent on this form of passive immunity until approximately 6 months of age when significant amounts of IgG are produced by the infant. Other antibody immunoglobulins, such as IgM and IgA, are larger than IgG and do not cross the placenta. Breast milk, however, contains a significant amount of secretory IgA that protects the infant from microbes in the maternal intestinal tract.

Gradually, the young infant will begin to produce adequate circulating antibodies of the IgG

class. This process takes time, and mounting the full antibody response to a foreign antigen is not possible until well into early childhood.

In summary, because of a variety of deficiencies in both natural and acquired immunities, the neonate is vulnerable to infection. Neonatal response to infection is sluggish and inadequate, leading to a predisposition to systemic rather than localized infections. Vaginal birth and breastfeeding both help establish healthy microbial colonization, an effect that persists throughout infancy. Breastfeeding has additional direct and indirect mechanisms that support and stimulate development of immunity in the newborn.

The Newborn Gastrointestinal Tract

The gastrointestinal system in a term newborn exhibits varying levels of maturity. Prior to birth, the term fetus exhibits sucking and swallowing motions. Mature gag and cough reflexes are intact at birth. Meconium, although sterile, contains debris from the amniotic fluid, which confirms that the fetus ingests amniotic fluid and that the fluid passes through the gastrointestinal tract.

The ability of the term newborn to ingest and digest exogenous food sources is limited secondary to varying amounts of digestive enzymes and hormones in all portions of the gastrointestinal tract. Newborns are less able to digest proteins and fats than are adults. Carbohydrate absorption is relatively efficient but still less than the adult ability. The newborn is particularly efficient in absorbing monosaccharides such as glucose, as long as the amount of glucose is not too large.

The cardiac sphincter—the juncture of the lower esophagus and the stomach—is incomplete at birth, which contributes to frequent regurgitation of stomach contents in newborns and young infants. The capacity of the stomach itself is limited, holding less than 30 mL in a term newborn.

The newborn's intestines are also relatively immature. Prior to birth, this organ is semi-dormant. Normal extrauterine transition includes a striking increase in blood flow and a decrease in vascular resistance that results in increased blood flow to the neonate's rapidly growing intestines.[48] The underlying musculature is thinner and less efficient in the newborn than in the adult, leading to unpredictable peristaltic waves. The folds and villi of the intestinal wall are not fully developed. The epithelial cells lining the newborn's small intestine do not have the rapid cell turnover that promotes most effective absorption. This immaturity of the intestinal epithelium affects the ability of the intestine to be protected from harmful substances, and the decreased vascular resistance increases the risk of damage subsequent to hypoxia, should hypoxia occur.[48]

During early infancy, the newborn faces the substantial task of "gut closure," the process by which the epithelial surfaces of the intestine become impermeable to antigens. Prior to gut closure, the infant is vulnerable to bacterial/viral infection as well as to allergenic stimulation through intestinal absorption of large molecules.

Among the defenses present in the GI tract are the chemical barriers of increased acidity, the digestive enzymes that break down large molecules, and the secretory IgA that lines the small intestine. Secretory IgA dampens inappropriate immune activation and binds with harmful antigens.[49,50] In the breastfed newborn, maternal secretory IgA restricts immune activation and bacterial attachments.[48] Unlike other types of immunoglobulin, secretory IgA is not absorbed and works at the local level in the intestine.[51]

The beginning of oral feedings stimulates the intestinal lining to mature via promotion of rapid cell turnover and production of microvillus enzymes such as amylase, trypsin, and pancreatic lipase. All enteral feedings, even in very small amounts, lead to helpful surges in gastrointestinal trophic factors—mainly hormones that lead to a full maturation in functioning.[52] The colon in the newborn conserves water less efficiently than that in the adult, which predisposes the newborn to complications from water loss. This makes a diarrheal

illness potentially serious in a young infant.

The Newborn Microbiome

In humans, the entire gastrointestinal tract serves as a component of the natural immune system, which collectively represents a system of defense for the host. Ongoing research on maternal and newborn microbiomes is replacing former theories of newborn bacterial colonization. Microbiomes flourish on the skin, in the mouth, and in the gut, and appear to influence digestion, the immune system, endocrine function, and possibly neurologic signaling.[53] At birth, the rapid colonization of the sterile fetal intestine with commensal bacteria performs valuable functions and prevents pathogenic bacteria from dominating this microbiota.

Following a vaginal birth, the first colonization is with maternal vaginal bacteria. Following a cesarean section birth, the first colonization is with bacteria from the operating room environment. Thus, after birth, the intestinal epithelium is exposed to trillions of bacteria. This diverse population of microbes is then involved in creating an effective barrier against bacteria in a process known as mucosal host–microbial homeostasis. The initial mucosal host–microbial interaction begins development of an intestinal microbiota that recognizes healthy bacteria and repels harmful ones.[49] These microorganisms also assist in digestion and breakdown of toxins, and the synthesis of vitamins.

Many factors have the potential to change neonatal microbiomes: maternal stress and diet, antibiotic exposure, cesarean birth, and infant diet. Differences have been demonstrated between preterm and term neonate microbiomes, between the microbiomes of newborns born vaginally and by cesarean section, between breastfed and formula-fed neonates, and between those exposed to antibiotics before and after birth and those unexposed to antibiotics. Research is being conducted on ideal ways of seeding the neonatal microbiome, such as exposing newborns born by cesarean section to maternal vaginal secretions. The outcomes of this emerging research are not conclusive enough yet to affect current newborn care practices.[53]

The Renal System

The term newborn has some structural and functional immaturity within the renal system, most of which resolves spontaneously during the first month of life.[54] The newborn kidney has less renal blood flow and a lower glomerular filtration rate compared to that of an adult. Tubular function is immature, which can lead to large sodium losses and other electrolyte imbalances.[55] The newborn is unable to concentrate urine very well, which is reflected in the low specific gravity (as low as 1.004) and osmolality of urine. All of these renal limitations are accentuated in the preterm infant. These aspects of renal function are typically only a problem for sick or stressed newborns. For example, if a newborn needs intravenous fluids or medications, the limitations of the still developing renal system increase the risk of iatrogenic fluid overload.[55]

The newborn excretes a small quantity of urine in the first 48 hours of life, often as little as 30 to 60 mL. This urine should not include any protein or blood. Large amounts of cellular debris may indicate injury or irritation within the renal system.

Conclusion

Newborn physiology comprises fascinating, dynamic, and rapidly changing systems that both protect the newborn during adjustment to extrauterine life and exhibit significant vulnerabilities to certain stressors such as cold and infection. Basic knowledge of newborn physiology can help midwives care for newborns and teach parents how to care for their infants as well.

Introduction

The complete newborn examination is composed of three parts: (1) a newborn history, (2) the gestational age assessment, and (3) the physical examination. Based on the results of this examination, the midwife will ascertain a newborn's level of wellness and identify potential or existing problems. A plan of care appropriate for that newborn and family can then be developed. This chapter reviews the basic newborn examination. An extensive guide to the content and findings of the newborn physical examination is provided in **Appendix 37A**.

Appreciation for the role of the newborn history and the gestational age assessment has grown in recent years. With new knowledge of genetic inheritance, genomics, fetal development, and the effect of maternal conditions on fetal well-being, it is now recognized that birth is merely a continuation of a life already influenced by many variables. An accurate history of these variables is a critical piece of the full assessment of the newborn.

Approach to the Newborn Examination

The goal in examination of the newborn is to maximize the amount of information gathered while minimizing distress to the newborn and parents. Parents usually show appropriate concern about any handling or examinations that cause their child to cry. It is best to examine the newborn approximately 1 hour after a feeding, when the infant is most likely to be content. The general order of the examination also should be modified based on infant status at the time of the examination. For example, if the infant is asleep or in a quiet alert phase, collection of assessments that benefit from this status—specifically heart rate and respiratory rate—should be performed first. Once these data are collected, more potentially upsetting examination techniques can follow.

Prior to starting a physical examination and gestational age assessment, the maternal records during pregnancy, labor and birth records, and neonatal records should be reviewed. The examination should be performed in an environment that provides proper lighting, cleanliness, and warmth. All equipment needed for the examination should be organized before beginning, including gestational age and physical examination forms (or access to an electronic health record), measuring tape and length growth chart, stethoscope, and ophthalmoscope. Familiarity with the correct use of equipment and the guidelines for accurate measurement is essential. As a case in point, a study published in 2009 reported that of 200 children admitted to a large, urban hospital, only 24% had their linear measurement plotted correctly.[1]

Prior to making any physical contact with the newborn, the goal and purpose of the examination is explained to the mother and/or family members and permission to handle the newborn is obtained. The midwife then performs a 20-second scrub of hands and forearms with a bactericidal soap. Nonsterile gloves also frequently are used by midwives to perform the examination, especially in hospital settings. During the examination, feedback can be offered to the parents about the strengths and attributes of their newborn as well as any significant findings. As part of this exchange, the midwife can provide the parents with information and further assess their readiness for infant care.

History

The prenatal and family history of a newborn is gathered through chart review and interviews with the mother and possibly other members of the newborn's family. As the information is gathered, the midwife develops a mental list of areas of potential concern, including environmental, genetic, social, maternal medical, perinatal, and neonatal factors.

Environmental and Genetic Factors

Environmental factors that influence the newborn can include occupational exposure of the mother or father to hazardous materials such as X rays, other radiation, solvents, infectious agents, fumes, and gases. In the home, environmental factors that can cause fetal or neonatal damage or illness include unsafe drinking water, ingestion of raw or undercooked meats, exposure to paints or solvents, infections transmitted by house pets or gardening activities, poorly ventilated heaters, living near a hazardous waste site, and exposure to toxins brought to the home from a family member's workplace.

Inquiring about the well-being of other children in the home and their ages is important to assess for exposure to illness that could affect the fetus prenatally such as varicella, cytomegalovirus (CMV), parvovirus, or other viral illness.

The genetic history should include information about any family members, alive or deceased, with physical or mental disorders or inherited diseases. Any family members with unexplained multiple pregnancy losses also should be noted. Current health status of the newborn's parents, siblings, and second-degree relatives (aunts, uncles) should be included.

Social Factors

The social history includes information about the woman's place of residence, access to transportation, and social supports. Information gathered includes who will be the designated caregiver and who lives in the home. If the woman has other children, the midwife should determine whether they live with her and, if not, the reason for their absence. Inquiring about the health and well-being of the children, paying particular attention to any accident patterns that may indicate abuse or neglect, is important as well. A key question used in the past to indicate the status of care received by other children in the home was those children's immunization status. As more families choose among various immunization schedules, the decision making regarding this topic should be further explored. Is the family making an informed decision regarding the immunization of their children, or is a lack of immunization due to neglect or another problem, such as lack of access to healthcare services?

Obtaining a description of the social environment is an opportune time to screen for substance use by the mother and other members of the newborn's household. Maternal exposure to even passive cigarette smoke may affect fetal development and growth,[2] while newborns and small children exposed to passive smoke are at risk for respiratory illness, including sudden infant death syndrome (SIDS).[3] Newborns living in a home where there is regular illicit substance use or overuse of prescription medications may also be vulnerable to

neglect. In addition, the possibility for exposure to violence, either direct or secondary, is increased in such a setting.

Maternal Medical and Perinatal Factors

Basic data about the newborn's mother include maternal age, last normal menstrual period, and expected date of birth. The adequacy of prenatal care should be noted, along with any prenatal problems listed in the prenatal record. All laboratory values and prenatal testing, including ultrasound reports, as listed in **Table 37-1** are reviewed.

Table 37-1 Prenatal Tests Reviewed Prior to Newborn Examination

Purpose of Test	Prenatal Screening Tests
Blood type	ABO blood type and Rhesus (Rh) type, antibody screen for isoimmunization
Maternal infection	Hepatitis B surface antigen, *Chlamydia trachomatis* screen, syphilis, group B streptococcus colonization test, human immunodeficiency virus (HIV) screen, *Neisseria gonorrhoeae*
Diabetes (including gestational diabetes)	Plasma glucose level as a screen for gestational diabetes, or hemoglobin A1c (HbA1c) if screened for type 2 diabetes
Birth defects	Carrier screening (e.g., cystic fibrosis), chromosomal anomaly screening (e.g., Down syndrome screening in first and second trimester), to diagnostic test (e.g., chorionic villus sampling or amniocentesis)
Fetal ultrasound	Fetal survey for morphology, amniotic fluid volume, gestational age
Substance abuse	Toxicology screen

A wide variety of maternal medical, prenatal, and intrapartum conditions can adversely affect the newborn's health and well-being. **Table 37-2** presents a selected list of maternal medical conditions and fetal and newborn implications that may be associated with those conditions.[4-13]

Table 37-2 Neonatal Complications Associated with Maternal Medical and Perinatal Conditions

Factor	Possible Newborn Complications
Maternal Medical Conditions	
Cardiac disease	Chronic intrauterine hypoxia
Diabetes (type 1 or type 2)[a]	Neonatal risks are directly related to the onset, duration, and degree of glucose dysregulation in the mother. Risks include congenital anomalies; miscarriage or stillbirth; perinatal asphyxia; intrauterine growth restriction; large for gestational age; polyhydramnios; birth injury, especially brachial plexus injury following shoulder dystocia; polycythemia; hyperbilirubinemia; hypoglycemia; and respiratory distress.
	Long-term: The infant has an increased risk of diabetes, obesity, and metabolic syndrome.
Hypertensive disorders[a]	Neonatal risks are directly related to the onset, duration, and degree of the mother's hypertension. Neonatal complications include intrauterine growth restriction, prematurity, abruptio placentae, stillbirth, and respiratory distress.

Renal disease	Prematurity, intrauterine growth restriction
Rh or other isoimmunization	Anemia, jaundice, hydrops fetalis
Seizure disorder requiring anticonvulsant therapy	Increased risk for congenital anomalies associated with some anticonvulsant drugs. Seizure disorder may independently increase the risk for numerous newborn morbidities including stillbirth, preterm birth, placental abruption, and preeclampsia.
Sexually transmitted infections	Perinatal transmission
Substance abuse	Neonatal abstinence syndrome
Prenatal Conditions	
Assisted vaginal delivery	Cephalohematoma, bruising, subgaleal hemorrhage
Gestational diabetes[a]	Neonatal risks are directly related to the onset, duration, and degree of glucose dysregulation in the mother. Risks include congenital anomalies; miscarriage or stillbirth; perinatal asphyxia; intrauterine growth restriction; large for gestational age; polyhydramnios; birth injury, especially brachial plexus injury following shoulder dystocia; polycythemia; hyperbilirubinemia; hypoglycemia; and respiratory distress. Long-term: The infant has an increased risk of diabetes, obesity, and metabolic syndrome.
Infection	Perinatal transmission
Oligohydramnios	Fetal growth restriction, amniotic band defects, dehydration syndromes, neonatal kidney/bladder abnormalities
Polyhydramnios	Neonatal kidney problems, tracheoesophageal fistula, other congenital anomalies
Size–dates discrepancy	Fetal growth restriction, macrosomia, birth trauma
Perinatal Events	
Abnormal presentation or position of fetus	Birth trauma
Acute fetal bradycardia (e.g., placental abruption, uterine rupture, prolapsed cord)	Intrauterine fetal demise, neonatal encephalopathy, neonatal hypovolemia, metabolic acidemia at birth (base excess [pH > 12]), cerebral palsy[b]
Cesarean birth	Fetal laceration, respiratory distress
Fetal intolerance of labor	Metabolic acidemia at birth (base excess [pH > 12]), neonatal encephalopathy
Intra-amniotic infection or maternal fever in labor	Neonatal sepsis
Meconium-stained fluid	Meconium aspiration pneumonia
Preterm birth	Neonatal risks are related to the degree of prematurity. Selected problems include both short-term and long-term morbidities such as neonatal intensive care unit admission, respiratory distress syndrome, and cerebral palsy.
Prolonged rupture	Neonatal sepsis

of membranes, term or preterm	
Postdates birth (> 42 weeks' gestation)	Postmaturity syndrome, meconium aspiration syndrome, neonatal intensive care unit admission
Operative vaginal birth: vacuum or forceps	Vacuum: Cephalohematoma, intracranial hemorrhage, subgaleal hemorrhage, retinal hemorrhage, shoulder dystocia
	Forceps: Skull fracture, facial nerve palsy, intracranial hemorrhage, subgaleal hemorrhage
Shoulder dystocia	Erb's palsy, fractured clavicle

Neonatal Factors

Valuable data from the immediate neonatal period include the Apgar scores at 1 and 5 minutes, umbilical cord artery pH and base excess values if obtained, and the duration of any resuscitation efforts performed immediately after the birth. Information that indicates an increased risk for perinatal asphyxia is important, as is evidence suggesting an increased risk for hypothermia/hyperthermia and hypoglycemia.

Newborn behaviors (noted in the health record) indicative of a healthy newborn transition include sucking, the ability to feed, alertness, voiding, and passage of meconium. Behaviors of concern include jitteriness, lethargy, poor or absent sucking, and unusual cry.

The results of laboratory tests performed in the birth room should be noted in the newborn history. Typically, these tests include peripheral glucose samples, hematocrit, and umbilical cord blood gases. The anatomic site from which blood samples were obtained should be noted, as this site will be assessed during the physical examination.

Gestational Age Assessment

Key components of both the gestational age assessment and the physical examination can be achieved by observation alone. Observation is particularly powerful and useful in newborn assessment. Judicious use of observation minimizes handling of the newborn and subsequent newborn agitation. If the newborn is ill, minimal touching and handling will allow the infant to conserve oxygen and glucose.

Scales for Gestational Age Assessment

Standardized forms of gestational assessment achieved a wide level of use after the publication of research by Dubowitz in 1970, which described a detailed examination of gestational age–related newborn attributes.[14] The Dubowitz examination combined assessment of both physical and neurologic characteristics.

In 1979, Ballard published a simplified method for assessing gestational age based on physical examination and neuromuscular assessment.[15] The Ballard Scale, based on the work of Dubowitz and others, involves less handling of ill newborns and relies less on a quiet, rested newborn for accurate results. This scale was revised in 1991 in an attempt to more accurately assess extremely premature newborns and provide more accuracy for term newborns.[16] It is now known as the New Ballard Scale, and has become the universal scale used to assess the gestational age of the newborn.

The New Ballard Scale (**Figure 37-1**) is accurate within a range of 2 weeks and can determine the gestational age of newborns as early as 20 weeks. This test is standardized and best performed by a trained examiner. Older studies have found that prior knowledge of the obstetric assessment of gestational age does not bias the examiner performing the New Ballard Scale.[17] Other studies have validated the New Ballard Scale as a reliable clinical tool until day 7 in the life of the moderately preterm infant, with neurologic signs being more reliable than strictly physical ones.[18] The New Ballard Scale does have some limitations. Most notably, it may overestimate gestational age compared with ultrasound or last menstrual period among infants with lower weight or gestational age, and among those newborns whose mothers received prenatal corticosteroid therapy.[19]

NEUROMUSCULAR MATURITY

	−1	0	1	2	3	4	5
Posture							
Square window (wrist)	> 90°	90°	60°	45°	30°	0°	
Arm recoil		180°	140°–180°	110°–140°	90°–110°	< 90°	
Popliteal angle	180°	160°	140°	120°	100°	90°	< 90°
Scarf sign							
Heel to ear							

PHYSICAL MATURITY

Skin	Sticky, friable, transparent	Gelatinous, red, translucent	Smooth, pink, visible veins	Superficial peeling and/or rash, few veins	Cracking, pale areas, rare veins	Parchment, deep cracking, no vessels	Leathery, cracked, wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel-toe 40–50 mm: −1 < 40 mm: −2	> 50 mm, no crease	Faint red marks	Anterior transverse crease only	Creases anterior two-thirds	Creases over entire sole	
Breast	Imperceptible	Barely perceptible	Flat areola, no bud	Stippled areola, 1–2 mm bud	Raised areola, 3–4 mm bud	Full areola, 5–10 mm bud	
Eye/Ear	Lids fused loosely: −1 tightly: −2	Lids open; pinna flat, stays folded	Slightly curved pinna, soft, slow recoil	Well-curved pinna, soft but ready recoil	Pinna formed and firm, instant recoil	Thick cartilage, ear stiff	
Genitals (male)	Scrotum flat, smooth	Scrotum empty, faint rugae	Testes in upper canal, rare rugae	Testes descending, few rugae	Testes down, good rugae	Testes pendulous, deep rugae	
Genitals (female)	Clitoris prominent, labia flat	Clitoris prominent, labia minora small	Clitoris prominent, labia minora enlarged	Labia majora and minora equally prominent	Labia majora large, labia minora small	Labia majora cover clitoris and labia minora

Figure 37-1 The New Ballard Scale (NBS).

Reproduced with permission from Ballard J, Khoury J, Wedig K, Wang L, Eilers-Walsman BL, Lipp R. New Ballard Scale, expanded to include extremely premature infants. *J Pediatr*. 1991;119:417.[16]

The New Ballard Scale takes approximately 2 or 3 minutes to perform, and its results should be recorded directly on the standardized form. It is best to record findings as the assessment is made, rather than relying on memory. After scores for each category of physical and neuromuscular maturity have been assigned, they are summed and the aggregate score is plotted to obtain gestational age.

The proper procedure for both the neuromuscular evaluation and the assessment of physical maturity is included in Appendix 37A. Accurate assessment using the New Ballard Scale

requires practice, and new examiners should have their examinations validated by a preceptor for several gestational age assessments with infants of different gestational ages.

Gestational Age Categories

When the physical maturity score and the neuromuscular maturity score on the New Ballard Scale form are added, the sum yields a gestational age determination. The newborn will then be classified into one of the following categories:[20-24]

1. *Preterm*: less than 37 *completed weeks' gestation*

Extremely preterm: less than 27 6/7 completed weeks' gestation

Very preterm: 28 to 31 6/7 completed weeks' gestation

Moderate preterm: 32 to 33 6/7 completed weeks' gestation

Late preterm: 34 0/7 to 36 6/7 completed weeks' gestation

2. *Term*: 37 to 42 completed weeks' gestation

Early term: 37 0/7 through 38 6/7 completed weeks' gestation

Full term: 39 0/7 through 40 6/7 completed weeks' gestation

Late term: 41 0/7 through 41 6/7 completed weeks' gestation

3. *Post-term*: more than 42 completed weeks' gestation

Small, Appropriate, and Large for Gestational Age

It is possible to estimate newborn health risks solely based on gestational age. By comparison, a more sophisticated relationship exists between gestational age and birth weight.[23] Within each of the categories of gestational age, there will be some newborns who are larger and some who are smaller. The extremes of accelerated and diminished growth are associated with certain newborn problems and predispositions.

At any gestational age, birth weights vary with altitude, race, country of origin, and socioeconomic class.[25] Thus, there is no international standard for normal birth weights for specific gestational ages.

The older charts that graph weight in relation to gestational age have limited utility because they determine gestational age based solely on the mother's menstrual history. More recent research has studied birth weight in comparison to a gestational age assigned by Ballard scores and ultrasound. Assessing birth weight in relation to gestational age will characterize the newborn as being in one of three categories:

1. Small for gestational age (SGA)
2. Appropriate for gestational age (AGA)
3. Large for gestational age (LGA)

After accurately categorizing the newborn into a gestational age and size-for-gestational age category, a plan can be developed to assess and manage potential problems that are associated with each of these categories.

Midwives generally care for term infants but may be involved in collaborative care of late preterm newborns (34 to 36 6/7 weeks' gestation) and early term newborns (37 to 38 6/7 weeks' gestation). Infants born in both of these gestational age categories are at higher risk for multiple respiratory conditions, problems with feeding, thermoregulation issues, jaundice, and death compared to infants born at term.[26,27]

Physical Examination of the Newborn

The physical examination of the newborn is designed to screen for physical variations, malformations, and the overall health of the newborn. There are many differences between the components of an adult physical examination and that of a newborn.

During examination of the newborn, the four basic techniques of physical examination—inspection, palpation, auscultation, and percussion—are used. The complete examination involves three types of evaluation: (1) anthropomorphic measurements, (2) evaluation of organ systems, and (3) neurologic evaluation.

When documenting findings, note any variations present, and avoid use of the nondescript phrase "within normal." Many minor newborn physical and behavioral variations fall within the normal range, so the specific terms and descriptions for newborn characteristics should be used where appropriate.

Approach to the Examination

Most textbooks and physical examination records assume an examination that proceeds from head to toe. This approach is not necessary, however, for a newborn. For example, if the newborn is quiet or sleeping, many examiners start the hands-on examination with auscultation of heart and bowel sounds and palpation of the femoral pulses. In an awake, alert newborn, the examiner may check the red reflex first.[28] A crying newborn presents the opportunity for inspection of the mouth and throat. Excessive handling can over-stimulate the newborn. The newborn may be calmed during an examination by being given a non-latex gloved finger or pacifier to suck on if the mother gives permission.

Anthropomorphic Measurements

Anthropomorphic measurements include the infant's length, as well as the chest and head circumferences. The newborn body has a unique appearance. Normally, the head circumference is larger than the chest circumference, the abdomen is protuberant, and the tone is flexed (**Figure 37-2**). Measurements should be performed using a standardized technique. The newborn length is most accurately assessed if the head of the newborn is flush against a firm surface. A mark often is made on the table paper to designate the top of the neonate's head. The newborn's legs are then extended and a mark made on the table paper where the heels rest when the legs are completely extended. After the newborn is moved, the distance between the mark from the top of the head and the mark placed at the heel is measured and documented in centimeters.

Figure 37-2 Normal newborn body proportions.

The newborn head circumference is measured around the head at the level of the occiput, parietal bosses, and just above the eyebrows. This measurement may decrease in the first week of life as caput succedaneum, cephalohematoma, or soft facial tissue swelling from birth recedes. Chest circumference is measured under the arms and across the nipple line.

The newborn's weight should be assessed on a scale with a drape between the newborn and the metal or plastic. This covering prevents conductive heat loss and minimizes infection from cross-contamination. The scale should be calibrated to account for the weight of the drape. **Table 37-3** lists mean birth weights, lengths, and head circumferences of term newborns (37–42 weeks) born in North America.[29] Newborn measurements vary by gestational age, sex, and parental ethnicity, with newborns having Asian heritage being the smallest at birth. Using correct measurement standards can prevent unnecessary testing for newborns incorrectly categorized as small for gestational age.

Table 37-3 Mean (and Standard Deviation) for Birth Weight, Length, and Head Circumference by Sex, Gestational Age at Birth, and Ethnicity

Gestational Age (weeks)	European Descent		Chinese Descent		South Asian Descent

Assessment for Birth Injuries

Birth injuries may occur during a long, protracted labor or a difficult birth. For example, they can be associated with situations in which the fetus is large or the fetal presentation/position is abnormal. Physical examination findings related to birth trauma include small scalp abrasions, bruises that correspond to forceps placement along the side of the face, brachial plexus injury to the arm, and fractures to bones, most often clavicle or extremities.

The skull bones are not fused in an infant and therefore they are somewhat mobile and able to conform to pressures from the maternal pelvic bones during the passage through the vaginal canal. A newborn skull that is not exactly round is a normal finding. Parents can be reassured that the skull will assume a normal newborn shape within a few days. Possible physical examination findings of the newborn head are depicted in **Figure 37-3**. There is often a soft tissue swelling (edematous collection of serosanguineous and subcutaneous fluid) called *caput succedaneum* that is visible on the area of the fetal head, which was the presenting part. Caput succedaneum has poorly defined margins, may cross suture lines, and is not markedly tense. In contrast, a *cephalohematoma* is a collection of blood under the periosteum of one of the cranial bones, usually the parietal bone. Unlike caput succedaneum or general edema, the blood does not cross the suture lines of the newborn skull because the bleeding is under the periosteum. Some cephalohematomas occur with linear skull fractures, most of which heal well. A *subgaleal hemorrhage* is an accumulation of blood below the scalp but above the periosteum. It is a rare but life-threatening complication because this space is large and the newborn can lose a great deal of blood very quickly. Signs include a diffuse swelling in the head that shifts independent of movement. In addition, the newborn will display symptoms of shock and hypovolemia.

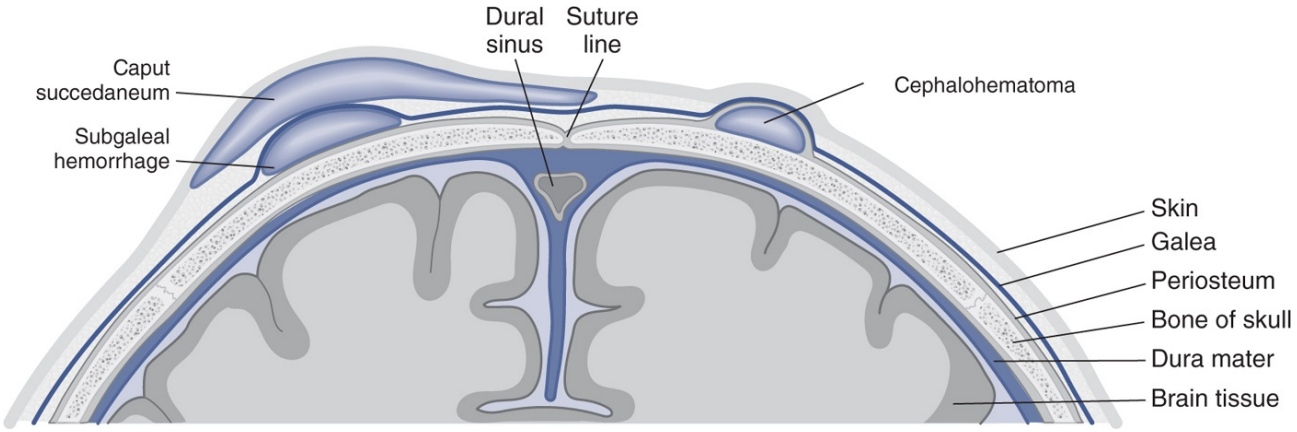

Figure 37-3 Anatomy of caput succedaneum, cephalohematoma, and subgaleal hemorrhage.

The signs of facial palsy—a temporary condition—include asymmetry of the face. The newborn with a brachial plexus injury may be in pain. The manifestations of the injury will depend on the nerve root that was injured and the degree of the injury. Nerve roots involved can include the cervical roots C5 and C6 (Erb-Duchenne paralysis), roots C8 and T1 (Klumpke's paralysis), or both.[30] The physical signs of Erb-Duchenne paralysis include a generalized loss of movement in the affected arm with an adduction of the lower part of the arm. This leads to the characteristic "waiter's tip" sign, involving an internal rotation of the lower portion of the arm with the finger and wrist flexed.[30] The grasp reflex is intact, but the Moro reflex is weak on the affected side. In Klumpke's paralysis, the grasp reflex is absent and the infant's hand is kept in a claw-like posture.[30]

Pressure and manipulation during the birth process may cause fractures of bones, although occasionally intrauterine fractures may occur. The bones most frequently affected include the clavicles and the extremities. Signs of bone fracture include swelling, skin discoloration, lack of movement, abnormal positioning, and pain with movement.[31] Crepitus occasionally can be elicited on palpation. The Moro reflex will be asymmetric.

Assessment for Birth Defects

Variations in physical appearance may be due to inconsequential human variation or familial traits. However, approximately 3% to 4% of live births involve some congenital defect—most minor, but some serious. Many genetic, chromosomal, multifactorial disorders are initially suspected or even diagnosed based on the newborn's physical appearance.

Many parents believe that normal prenatal tests provide assurance that their fetus is normal. Unfortunately, all prenatal tests have limitations, and it is important to explain to new parents that most prenatal tests are screening tools meant to identify an increased risk for specific common disorders rather than being either diagnostic or able to detect all possible birth defects. The newborn examiner must inform parents about any potential problems detected during the examination and refer to a specialist for more extensive evaluation.

Most minor malformations (**Table 37-4**), when found in isolation, are simple physical variants. However, the presence of three or more minor malformations is suggestive of a major

underlying malformation, and requires further evaluation.[30] For example, epicanthal folds may be normal by themselves, especially for infants of Asiatic descent. In combination with a transverse palmar crease and low-set ears, however, genetic evaluation for a possible trisomy is warranted.

Table 37-4 Common Minor Malformations Noted on a Newborn Examination

Large fontanel
Epicanthal folds
Hair whorls
Widow's peak
Low posterior hair line
Preauricular tags and pits
Minor ear anomalies: protruding, rotated, low-set
Darwinian tubercle (thickening of ear on helix at junction of upper and lower thirds)
Digital anomalies: clinodactyly (curved finger); camptodactyly (bent finger); syndactyly (webbed finger)
Transverse palmar crease
Shawl scrotum (scrotum surrounds penis)
Redundant umbilicus
Widespread nipples
Supernumerary nipples

With the routine use of prenatal ultrasound, many physical malformations of the fetus may already have been detected during the prenatal period. However, the accuracy of ultrasonography can be compromised by numerous factors (e.g., technician experience level, fetal position during sonogram), which may lead to many subtle malformations going undetected until the infant's birth. **Table 37-5** lists visual clues that may be noted during physical examination and the serious conditions that they may indicate.[30] Early evaluation and intervention can help prevent serious sequelae of malformations such as infection, intestinal perforation, spinal cord injury, or intellectual disability.

Table 37-5 Visual Clues That Suggest Birth Defects and Genetic Conditions

Diagnosis	Possible Visual Clues
Autosomal Dominant (Mendelian Inheritance)	
Neurofibromatosis I	Café-au-lait spots
Tuberous sclerosis	Ash leaf spot: hypopigmented areas of skin
Myotonic dystrophy	Myopathic facies
Waardenburg syndrome	Facial abnormalities, with diminished coloration of hair, skin, and iris
Van der Woude syndrome	Cleft palate, cleft lip, and depression of lower lip
Holt–Oram syndrome	"Heart-hand syndrome": heart and upper limb abnormalities
Autosomal Recessive (Mendelian Inheritance)	
Tay–Sachs disease	Cherry red spot in macula of eye
Galactosemia	Cataracts and neonatal jaundice
Cystic fibrosis	Meconium ileus, rectal prolapse
Congenital adrenal hyperplasia	Ambiguous genitalia
Mucopolysaccharidoses	Corneal clouding, joint contracture
Meckel–Gruber syndrome	Polydactyly, encephalocele
Rhizomelia chondrodysplasia	Short proximal limbs, cataracts
X-Linked Recessive (Mendelian Inheritance)	
Fragile X syndrome	Large testes
Duchenne muscular dystrophy	Large calf muscle
Menke kinky hair syndrome	Steel-wool-like hair
Usher syndrome	Retinitis pigmentosa
Lesch-Nyhan syndrome	Gravel urine (sediment and calcifications in urine)
Mitochondrial (Non-Mendelian Inheritance)	
Kearns–Sayre syndrome	Muscle weakness, ophthalmoplegia (paralysis or weakness of eye muscles)
Leber's hereditary optic neuropathy	Muscle weakness, ophthalmoplegia
MELAS syndrome	Muscle weakness, ophthalmoplegia
MERRF syndrome	Muscle weakness, ophthalmoplegia
Uniparental Disomy (Non-Mendelian Inheritance)	
Prader–Willi syndrome	Obesity, small hands and feet
Gonadal Mosaicism (Non-Mendelian Inheritance)	
Osteogenesis imperfecta	Blue sclera

Diagnosis	Possible Visual Clues	Diagnosis	Possible Visual Clues
Teratogen(s)		**Chromosomal Abnormalities**	
Alcohol	Microcephaly, short palpebral fissures	Trisomy 21	Hypotonia, single palmar crease, prominent tongue
Nicotine (smoking)	Small for gestational age	Trisomy 18	Finger and joint contracture, webbed neck
Dilantin (Phenytoin)	Nail hypoplasia	Trisomy 13	Polydactyly, cleft palate, scalp defects
Carbamazepine (Tegretol)	Neural tube defects	Turner syndrome (45 XO)	Short stature, webbed neck
Warfarin (Coumadin)	Flat nasal bridge	Klinefelter syndrome (47XXY)	Small testes, gynecomastia
Isotretinoin (Accutane)	Facial and limb anomalies	Cri-du-chat syndrome (chromosome 5p deletion syndrome)	Natal mewing
Multifactorial		**Sporadic Multiple Pattern Syndrome**	
Clubfoot	Twisted foot	Cornelia de Lange syndrome	Synophrys (single eyebrow meeting in middle of face), phocomelia (underdeveloped limbs)
Cleft lip/palate	Nonjunction of lip or palate or both	Rubinstein–Taby syndrome	Large thumbs and great toes
Neural tube defects	Spina bifida, anencephaly, encephalocele	Williams syndrome	Elfin facies
Dislocated hip	Legs of different length, hip click on examination but may be asymptomatic	Sturge–Weber syndrome	Nevus flammeus
Congenital heart defect	Heart murmur, acrocyanosis, circumoral cyanosis	VACTERL association or VATER syndrome[a]	Tracheoesophageal fistula, imperforate anus, limb defects
Hypospadias	Urethral opening is on underside of penis		

Abbreviations: MELAS, mitochondrial encephalopathy, lactic acidosis, and stroke-like seizures; MERRF, myoclonic epilepsy with ragged red fibers.

[a] VACTERL and VATER refer to the types of defects that may be apparent at birth: vertebral, anus, cardiac, tracheoesophageal, renal, and limb.

Modified with permission from Wardinsky T. Visual clues to diagnosis of birth defects and genetic disease. *J Pediatr Health Care.* 1994;8(2):63-73.[30]

Newborns with ambiguous genitalia present a challenge. These newborns have external genital characteristics of both males and females. If the examiner has doubts about the genitalia, an immediate consultation with a neonatal team is indicated. In some instances, ambiguous genitalia are associated with congenital adrenal hyperplasia—a condition that will cause life-threatening dehydration shortly after birth. The team will measure the clitoris or phallus. This measurement will be used, along with other physical characteristics of the genitalia, to describe the virilization as in categorized in Prader staging.[32] The findings and arrangement for follow-up care will be discussed with the family. In some cases, these families will be encouraged to avoid assigning a sex to the newborn.

Complete assessment of an infant with physical variations should be performed by a team that includes specialists such as a neonatologist, a geneticist, an endocrinologist, and the nurse who is caring for the child. Some common abnormalities may be confirmed with rapid testing within 48 hours, but unfortunately it may take weeks before a comprehensive genetic karyotype is complete. Extensive additional testing may be necessary to evaluate the type and extent of the malformation. When a physical variation of concern is detected, the midwife's role is to obtain consultation and support the family.

The Neurologic Examination

The procedure of assessing reflexes, cranial nerves, and special senses is integrated into the overall physical examination outlined in Appendix 37A. The neurologic examination is an indicator of the integrity of the nervous system. Both diminished (hypo) and accentuated (hyper) responses are cause for concern. Diminished response can result from a congenital absence of a nerve, damage to sensory or motor pathways, or infection. Diminished or accentuated response to stimulation can also reflect a central neurologic deficit.

During the neurologic examination, assessments are made of the newborn's senses, including sight, hearing, and smell. Poor or absent response to oral, auditory, or olfactory stimulation may indicate nerve damage.

An absent or diminished response to an elicited reflex may be an indication of a variety of conditions.[33,34] Sometimes the reflex is partial or diminished because of newborn depression secondary to medications or infection. In other cases, the response may not be optimal because the sensory pathway conducting the stimulation has been damaged, reflecting a spinal or central nervous system lesion. Sometimes a reflex cannot be elicited because of temporary motor nerve damage that prevents the muscles in the affected area from responding to stimulation, as with a weak palmar grasp after a breech delivery or facial nerve paralysis after a forceps delivery (**Figure 37-4**). Sometimes damage is permanent, as in some brachial plexus injuries and some spinal cord defects. The following reflexes are elicited as part of the physical examination and are described in detail in Appendix 37A:

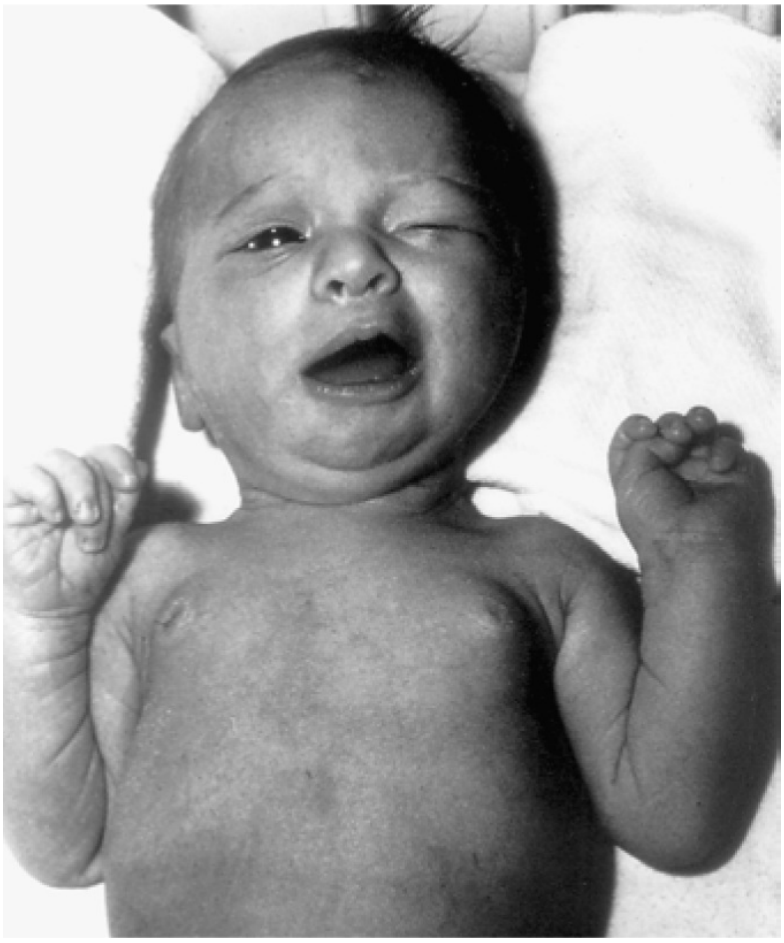

Figure 37-4 Facial nerve paralysis.

1. *Eyes*: pupillary reflex, red reflex, doll's eye reflex, blink reflex
2. *Upper extremities*: palmar grasp reflex
3. *Lower extremities*: patellar reflex, plantar reflex, Babinski reflex (**Figures 37-5** and **37-6**)

Figure 37-5 Plantar reflex.

Figure 37-6 Babinski reflex.

4. *Torso*: anal wink, tonic neck reflex

Absent, markedly diminished, or accentuated reflexes and asymmetrical reflexes should be noted on the physical examination form, and consultation with a pediatric provider about further testing and follow-up initiated.

One of the most commonly used evaluations of the neurologic status of the newborn is the Moro reflex, also known as the embracing reflex. As is true for the other primitive reflexes, the

Moro reflex is mediated by the brain stem and becomes apparent at approximately 25 to 26 weeks' gestational age.[34] Once thought to reflect an infant's effort to cling to or "embrace" its caregiver, it is now more commonly seen as an involuntary motor response meant to protect the infant from sudden changes in body displacements.[34-36] In normal infants, the response is symmetrical and disappears by 3 to 4 months. The Moro reflex consists predominantly of abduction and extension of the arms with hands open, and the thumb and index finger semiflexed to form a "C". Leg movements may occur, but they are not as uniform as the arm movements. With return of the arms toward the body, the infant either relaxes or cries. In comparison, a "startle pattern" (or reaction) is primarily a flexion rather than an extension response to sudden stimulation, and becomes more pronounced and regular as the infant matures, rather than diminishing.[33,34] Acceptable ways to elicit a Moro reflex that avoid eliciting a "startle pattern" include the following:

1. While the child is in a semi-sitting position, allow the infant to fall backward onto the examiner's open hand from an angle of 30 degrees.
2. While holding the infant in a horizontal position with both hands, quickly lower the infant approximately 10 to 20 cm, and come to sudden halt.[33]

As one of the primary primitive reflexes, any deviations found in the Moro reflex necessitate a pediatric consultation at a minimum and possibly a full neurologic work-up, especially if deviations in other reflex tests are also found. Sample deviations of the Moro reflex and their possible etiologies include the following:

- Absence of the reflex may indicate intracranial lesions.
- Asymmetrical response may indicate birth injury involving the brachial plexus, clavicle, or humerus.
- Abnormal persistence of embrace gesture may indicate hypertonicity.
- Persistence of the entire Moro reflex after 4 months may indicate delay in neurologic maturation.

Becoming Confident at Newborn Physical Examination

Many intricacies and nuances are involved in conducting and assessing a complete newborn examination. Recognition of normal as well as possible deviations is an essential skill for any clinician involved in the care of infants. While many academic sources are available for reference and review,[37,38] they cannot substitute for multiple clinical experiences involving the observation and examination of many newborns.

Findings	Significance	MOE	Notes
Color			Indicative of overall status of infant, especially cardiopulmonary system
In light-skinned infants: Body and mucous membranes should be pink In dark-skinned infants: Mucous membranes should be pink	No cardiopulmonary compromise	I	
Acrocyanosis of hands and feet during first 24 hours of life	Sluggish peripheral circulation caused by transition to the cool extrauterine life	I	*Definition:* Acrocyanosis—a blue or purple mottled discoloration of the extremities, especially the fingers, toes, or nose
Reddish hue	Adjustment in oxygen levels in extrauterine environment	I	Especially noted immediately after birth
Ecchymosis over presenting part	Pressure over presenting part, causing bruising and trapping of blood in external tissue layers	I	*Definition:* Ecchymosis—the escape of blood into the tissues from ruptured blood vessels marked by a livid black-and-blue or purple spot or area *Technique:* To differentiate between cyanosis and ecchymosis, apply pressure to darkened area; cyanotic area will blanche, ecchymotic area will remain dark
Mongolian spots over buttocks, with possible extension to sacral region	Hyperpigmentation	I	*Normal variation*, especially if found in dark-skinned infants
Jaundice after first 48 hours of age, receding by days 4–5	Physiologic jaundice	I	*Definition:* Physiologic jaundice—transition of blood supply to liver, increased RBC count with decreased lifespan of cells, decreased plasma protein level, and decreased glucuronyl transferase that aids in bilirubin conjugation *Prematurity:* Peak in jaundice may occur later

General Appearance			Indicative of nutritional status, infant maturity, and general well-being
Well-formed and rounded, with presence of subcutaneous tissue No obvious anomalies	Good nutritional status; generally healthy	I	
Vernix	Increases with gestational age	I	*Definition:* Vernix—a pasty covering chiefly of dead cells and sebaceous secretions that protects the skin of the fetus
Lanugo	Decreases with gestational age	I	*Definition:* Lanugo—a dense cottony or downy growth of hair; specifically, the soft downy hair that covers the fetus of some mammals *Technique (NBS):* Check lanugo on the back with a direct light to get a clear view
Posture			
Newborn position: • Fists clenched • Arms adducted, flexed • Hips abducted • Knees flexed • Flexion moves upward to arms • Spinal column straight		I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* "Frog position" of legs
Movement: • Spontaneous, symmetrical, may be slightly tremulous • Flexion and extension should be equal bilaterally	Full-term newborn activity	I	*Definition:* Tremulous—jerky motions, unequal movement *Prematurity:* No movement or asymmetrical, irregular, tremulous
Muscle Strength and Tone			
Strength and tone: Strong	May be full term	I	*Prematurity:* Strength and tone weak, hypotonia, or flaccid
Palmar grasp: Strong	Good overall strength; may be full term	I	*Prematurity*: Palmar grasp weak
Alertness and Cry			
Mood: • Ranges from quiet to alert • Consolable when upset	Normal newborn activity	I	*Prematurity:* Not easily aroused, not very alert
Cry: Strong	No increased intracranial pressure	I	
Moro (embracing) reflex: • Symmetrical • Disappears by 2–4 months		I/Pa	*Definition:* Consists predominantly of abduction and extension of the arms with hands open and the thumb and index finger semiflexed to form a "C". Leg movements may occur, but they are not as uniform as the arm movements. With return of the arms toward the body, the infant either relaxes or cries.

Alertness and Cry			
			Technique: Acceptable ways to elicit a Moro reflex include the following: • While the child is in a semi-sitting position, allow the infant to fall backward onto the examiner's open hand from an angle of 30 degrees • While holding the infant in a horizontal position with both hands, quickly lower the infant approximately 10–20 cm and come to sudden halt
Cardiopulmonary System			
Respiratory effort: • Easy, unlabored rhythm • May be irregular, but periods of apnea < 15 seconds Abdominal breathing	No respiratory distress or difficulty	I	
Respiratory rate: 40–60 breaths per minute	Normal rate	I	*Variation on normal:* Tachypnea in cesarean section or in full-term infants may be transient from retention of lung fluid *Prematurity:* Apnea > 15 seconds and accompanied by duskiness, cyanosis, or respiratory rate > 60 breaths per minute
Thorax: Symmetrical excursion	Normal respiratory pattern	I	*Definition:* Excursion—one complete movement of expansion and contraction of the lungs and their membranes (as in breathing)
Anteroposterior diameter: Normal	Normal respiratory pattern	I	
Breath sounds: • Clear • Equal bilaterally, anteriorly, and posteriorly • Occasional rales in first 24 hours	Clear lung fields	A	*Variation on normal:* Occasional rales may be present the first few hours after birth because of residual fetal lung fluid; no color changes or cyanosis should accompany this finding
Heart rate: • 100–160 bpm • Regular rate and rhythm • Without murmurs or only initial slight murmur	Normal cardiac rhythm without significant abnormalities	A	*Variation on normal:* Initial, slight murmur, usually heard at left sternal border or above apical pulse; may persist until the ductus arteriosus closes *Prematurity:* Bradycardia < 100 bpm or tachycardia > 160 bpm; murmur
Cranium/abdomen: No bruit	No arteriovenous malformation	Pa	*Definition:* Bruit—any of several generally abnormal sounds heard on auscultation
Apical pulse: At fourth or fifth intercostal space, mid-clavicular line, left anterior chest	Normal position of cardiac pulse; no shifting; without cardiomegaly		*Variation on normal*: Point of maximum impulse at the fourth intercostal space just right of the mid-clavicular line may be shifted to the right during the first few hours of life
Thrill: None present after first few hours of life	No increased cardiac activity	Pa	*Definition:* Thrill—an abnormal fine tremor or vibration in the respiratory or circulatory systems felt on palpation

Cardiopulmonary System			
Blood pressure: • Average systolic rate ◆ 28–32 weeks: 52 mm Hg ◆ 32–36 weeks: 56 mm Hg ◆ Full term: 63 mm Hg Equal in all 4 extremities	Normal cardiac output; good circulation; possibly no cardiac defect	Pa	
Tympany: Not increased over lung fields	Normal lung field borders	Pe	*Definition:* Tympany—a resonant sound heard in percussion
Skin			
Moist Warm to touch No peeling, wrinkles, edematous or shiny/taut skin	Normal, well hydrated	I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Variation on normal* (unless other abnormal findings are also present): Nevus flammeus; meconium staining; petechiae; skin tags *Prematurity:* Gelatinous with visible veins (transparent skin and visible veins disappear with increasing gestational age) *Postmaturity:* Dry, peeling, cracked
Vernix: Present	Increases with gestational age	I	*Definition:* See above *Prematurity:* No vernix
Lanugo: Scant	Full term Decreases with gestational age	I	*Definition:* See above *Prematurity:* Abundant lanugo
Milia	Common in newborns	I	*Definition:* Milia—a small, pearly, firm, non-inflammatory elevation of the skin due to retention of keratin in an oil gland duct blocked by a thin layer of epithelium
Erythema toxicum	Newborn rash over body, usually on days 1–3	I	
Mottling	May be normal reaction to immaturity of organ systems, if infant is of normal temperature, without color changes or bradycardia	I	
Temperature: • Warm • Axillary temperature 35.5–37.0°C	Normal range	P	*Prematurity:* Temperature may be cool (< 35.5°C) or warm (> 37°C)
Head			
Normocephalic in proportion to body (head circumference for average full-term newborn is 32–38 cm)	Normal	I	
Molding: Cranial distortion lasting < 5–7 days	Excessive pressure on cranium during vaginal delivery	I	

Head			
Overriding sutures	Excessive pressure on cranium during vaginal delivery	I	
Caput succedaneum	Edematous region of scalp extending over suture lines, resulting from pressure on the presenting part during vaginal delivery	I	
Head lag: ≥ 10 degrees in full-term infant Able to support head	Head lag: Decreases with maturity	I	*Technique:* Pull newborn up, supporting the arms, from supine to sitting position; grade degree of head lag by position of head in relationship to trunk *Prematurity:* Head lag > 10 degrees; little or no support of head
Hair distribution: Over top of head, with single strands identifiable	Full term	I	*Prematurity:* Fine, fuzzy, may be over entire head
Without masses or soft areas over skull bones	Normal	Pa	*Variation on normal:* Masses or soft areas such as craniotabes over parietal bones may be normal if no abnormality is present *Definition:* Craniotabes—thinning and softening of the infantile skull in spots
Bruit: None	Normal	A	*Definition:* See above
Fontanelles			
Anterior fontanelle: • Open until 12–18 months • Diamond shaped • Approximately 5 × 4 cm • Found along the coronal and sagittal sutures	Normal	I/A	
Posterior fontanelle: • Triangle shaped • Approximately 1 × 1 cm • Found along sagittal and lambdoidal suture lines	Normal May be closed at birth	I/A	
Facies			
Eyes: • On line with ears • Normal distance between eyes (approximately 2.5 cm) • Unworried expression	Normal	I	
Nose: Midline	Normal	I	
Oral Cavity			
Mouth: • Midline on face, symmetrical without drooping or slanting unilaterally with crying or other movement of mouth • Shape and size in proportion with face	Normal	I	

Oral Cavity			
Mucous membranes: Moist, pink	Well hydrated and oxygenated	I	
Chin: Shape and size in proportion with face	Normal	I	
Lips: Completely formed, pink, moist	Normal	I	
Palate: No arching; intact	Normal	I/Pa	
Tongue: • Size in proportion with mouth • Midline	Normal No neurologic dysfunction	I	
Uvula: Midline rises with crying	Normal function of glossopharyngeal and vagus nerves	I	
Gag reflex: Present	Normal neurologic function of glossopharyngeal and vagus nerves	I	*Physiology:* Reflexes generally develop from head to toe during gestation
Sucking reflex: Present and strong	Normal maturity and intact hypoglossal nerve	I	*Technique:* Offer non-latex gloved finger or nipple to test *Prematurity:* May be absent
Rooting reflex: Present	Normal maturity and intact trigeminal nerve	I	*Technique:* When cheek is stroked, infant turns toward stroking *Prematurity:* May be absent
Salivation: Without excess	Normal	I	
Nose			
Position: Midline	Normal	I	
Nares: Bilaterally present	Intact	I	
Nares: Patent	Normal	I	*Technique:* Occlude neonate's nostrils one at a time while holding mouth closed; infant should be able to breathe through one side at a time; passing a catheter into newborn's nares, one at a time, also demonstrates patency
Nares: Grimace or cry in response to strong odors passed under nose	Normal; intact olfactory nerve	I	
Nares: Breathing detected bilaterally	Patent	A	*Technique:* With a stethoscope, auscultate for breathing one side at a time
Eyes			*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1
Sclera: Clear	Normal	I	
Conjunctiva: Clear	Normal	I	
Iris: Colored evenly, bilaterally	Normal	I	*Variation on normal:* Brushfield's spots (these gold flecks may be normal if not found with other anomalies)
Pupils: Equal bilaterally and reactive to light	Normal; intact oculomotor nerve	I	*Technique:* Examination is done in a darkened room with penlight or flashlight; if done with a newborn in an incubator or in the nursery, shield the infant's eyes as much as possible

Eyes			
Cornea: Clear	Normal; intact	I	*Prematurity:* Hazy
Retina: Transparent	Normal; intact	I	
Lacrimal duct: Patent	Normal	I	*Definition:* Lacrimal duct—any of several small ducts that carry tears from the lacrimal gland to the fornix of the conjunctiva
Blink reflex: Reactive	Intact optic nerve	I	*Technique:* Responds to bright light
Red reflex: Present	Lens intact	I	*Technique:* Hold a direct ophthalmoscope close to the examiner's eye with the ophthalmoscope lens power set at 0. In a darkened room, the ophthalmoscope light should then be projected onto both eyes of the child simultaneously from approximately 18 inches away. To be considered normal, a red reflex should emanate from both eyes and be symmetric in character. *Variation on normal:* Transient opacity from mucus in the tear film that is mobile and completely disappears with blinking
Eyelids: Without edema, ptosis, or epicanthal folds	Normal; intact oculomotor nerve	I	*Definition:* Ptosis—a drooping of the upper eyelid *Definition:* Epicanthic fold—a prolongation of a fold of the skin of the upper eyelid over the inner angle or both angles of the eye
Doll's-eye response: Present	Normal: Intact trochlear, abducens, and oculomotor nerves	I	*Technique:* With the infant in supine position, turn the head from one side to the other; eyes move to the side opposite the side to which the head is turned
Eye position: Without slant	Normal	I	
Ears			*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1
Position: In straight line with eyes; vertical angle that is greater than straight vertical line; without slant	Normal	I	
Skin tags: Absent	Normal	I	
Cartilage formation: Well-curved pinna, sturdy, stiff cartilage, instant recoil	Normal	I/Pa	*Technique:* Palpate the entire pinna of the ear for the presence of cartilage *Prematurity:* Cartilage flattened or folded with slow recoil
Hearing: Neonate startles or cries in reaction	Normal; intact auditory nerve	I	*Technique:* Use a loud noise or snapping fingers to elicit response
Otoscopic examination: • Umbo (cone) of light present, pearl-gray tympanic membrane may have vernix • Membrane is movable without bulging	Normal; intact ear without infection	I	*Technique:* This examination is often omitted because it is difficult to perform and may be potentially harmful if the examiner is not skilled; ear should be pulled down and back for examination
Neck			
Shape: Symmetrical	Normal	I	*Variation on normal:* Asymmetrical shape may be due to fetal position in utero

Neck			
Head: • Turns from side to side equally, full range of joint motion • Shape symmetrical	Normal	I	
Length: Short, without excessive skin	Normal	I	
Tonic neck reflex: Asymmetrical and present but decreases	Normal	I	*Technique:* Place the infant in supine position; turn the head to one side with the body restrained; extremities on the side to which the head is turned are extended, but extremities on the other side are flexed; newborn's attempt to right the head when turned to the side tests the accessory nerve *Prematurity:* May be asymmetrical and strongly present
Thyroid: Midline	Normal	P	
Lymph nodes: Not palpable	Normal	P	
Masses: None	Normal	P	
Carotid: Pulse rate strong and regular	Normal cardiac and circulatory function	P	*Technique:* Do not massage the carotid artery or neck, as this action can result in reflex bradycardia
Clavicles: • Even and without "lumps" along bones • Symmetrical	No fractures	P	
Abdomen and Thorax			
Chest circumference: 30–36 cm	Average for full-term neonate	I	*Prematurity:* Chest circumference < 30 cm
Diaphragm: Equal excursion	Normal	I	
Ribs: Symmetrical	Normal	I	
Breast: Nipple spacing on line without extra nipples	Normal	I	*Variation on normal:* Extra nipple
Areola: Raised and without discharge	Full term	I	*Variations on normal:* Flat areola, discharge, or hypertrophy may be due to maternal hormonal influence *Prematurity:* Flat areola and/or discharge
Abdomen: Rounded, contoured, symmetrical	Normal	I	*Technique:* To document distension accurately, measure the abdominal girth every 4 hours to detect changes *Prematurity:* Abdominal edema or distension may be present
Umbilical cord: • 3 vessels (2 arteries, 1 vein) • Bluish white color	Normal	I	*Variation on normal:* 2 vessels (1 artery, 1 vein)
Abdominal musculature: Strong	Normal	I	
Peristaltic waves: Not visible	Normal bowel activity	I	
Bowel sounds: Present	Normal	A	
Abdomen: No bruit	Normal	A	

Abdomen and Thorax			
Renal: No bruit	Normal	A	
Xiphoid process: Present	Normal; intact	Pa	
Ribs: Without masses or crepitus	Intact, without defects or "air leaks"	Pa	*Definition:* Crepitus—grating or crackling sound or sensation (like that produced by the fractured ends of a bone moving against each other)
Breast tissue: 1 cm	Normal: Full term	Pa	*Technique (NBS):* Palpate to accurately assess breast tissue *Prematurity:* Breast tissue may be < 1 cm and as little as 5 mm
Abdomen: • Soft • Nontender • Without masses	Normal	Pa	*Prematurity:* Separation of abdomino-rectus muscles (diastasis recti) is common
Kidneys: • 4–5 cm in length • Right kidney lower than left • Found in abdomen and posteriorly in lumbar or flank area	Normal	Pa	*Technique:* Palpate with the newborn's legs flexed in a fetal position to relax the infant
Liver: • Sharp edge just above right costal margin • Firm	Normal	Pa	
Spleen: 1 cm below left costal margin	Normal	Pa	
Bladder: Not distended	Normal kidney and urinary tract system	Pa	*Technique:* Be sure to evaluate immediately post void or may be falsely evaluated as distension
Groin: • Femoral pulse rate strong and regular bilaterally • No hernias or masses	Normal	Pa	
Gastric bubble: • Just below left costal margin and toward midline • Tympanic	Normal	Pe	
Abdomen: Tympanic except dull over liver, spleen, and bladder	Normal liver, spleen, bladder, no masses (indicated by dullness)	Pe	*Technique:* Be sure to examine post-void
Genitourinary Tract, Female			
Labia majora: Present and extend beyond labia minora	Full term	I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* Labia majora smaller than labia minora
Labia minora: Present and well formed	Full term	I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* Labia minora larger than labia majora
Clitoris: Present, may be enlarged	Full term	I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* May also be enlarged

Genitourinary Tract, Female			
Urethral meatus: Present in front of vaginal orifice	Normal	I	
Vagina: Patent with or without white discharge	Normal	I	*Variation on normal:* Slight bleeding related to maternal (?) hormonal influence
Genitalia: Distinguishable as female or male	Normal	I	
Perineum: Smooth	Normal	I	
Anus: Midline, patent	Normal	I	*Technique:* Test by gently attempting to insert small non-latex gloved finger
Anal wink: Present	Normal sphincter	I	*Technique:* Light stroking of anal area produces constriction of sphincter
Genitourinary Tract, Male			
Penis: • Straight • Proportionate to body • Length: 2.8–4.3 cm	Normal	I	
Urinary meatus: Midline At tip of glans	Normal	I	*Technique:* If male neonate is uncircumcised, gently retract the foreskin. If circumcised, also check for edema or bleeding.
Urinary stream: Straight from penis	Normal urinary pattern	I	First void should occur within 24 hours after birth
Testes and scrotum: Full, numerous rugae	Full term	I	*Technique (NBS):* With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* Testes and scrotum may be flaccid, smooth, or with few rugae
Pigmentation: Dark	Normal	I	
Perineum: Smooth	Normal	I	
Anus: • Midline • Patent	Normal	I	*Technique:* Test by inserting small non-latex gloved finger
Anal wink: Present	Normal sphincter	I	*Technique:* Light stroking of anal area produces constriction of sphincter
Testes: Descended on at least one side	Full term	Pa	*Variation on normal:* Undescended testes *Prematurity:* Testes not palpable, though they may be found high in the inguinal canal
Upper Extremities			
Length: • In proportion to each other • Lower extremities and body symmetrical	Normal	I	
Full range of joint motion, including: • Abduction • Adduction • Internal and external rotation • Flexion • Extension as applicable to joint	Normal	I	*Physiology:* Full flexion of upper extremities comes with maturity *Prematurity:* • Limited range of joint motion • Limited range of flexion

Upper Extremities			
Shoulder: Full range of motion and flexion	Normal	I	
Clavicles: Full range of motion and flexion	Normal	I	
Elbow: Full range of motion and flexion	Normal	I	*Variation on normal:* Limited range of motion or flexion of the elbow may be related to fetal position in utero
Wrist: Square window test	Normal	I	*Technique (NBS):* Test for square window by flexing the infant's wrist on the forearm, then measure the angle according to gestational examination chart (i.e., 0-degree angle for term neonate); exert pressure sufficient to get as much flexion as possible *Variation on normal*: Limited range of motion or flexion of the wrist may be due to fetal position in utero *Prematurity:* • Limited range of motion or flexion of the wrist • Square window angle > 0 degrees
Hand–grasp reflex: Present, strong, equal bilaterally	Normal; maturity	I	*Variation on normal:* Weak, absent, or unequal grasp reflex may be due to fetal position in utero *Prematurity*: Hand–grasp reflex may be weak or absent, or unequal bilaterally
Scarf sign: Elbow short of midline	Maturity	I	*Technique (NBS):* With the infant supine, take the infant's hand and draw it across the neck and as far across the opposite shoulder as possible. Assist the elbow by lifting it across the body. Observe the position of the elbow to the chest. Grade the position according to the gestational chart. *Prematurity:* Scarf sign—elbow beyond midline
Arm recoil	Maturity	I	*Technique (NBS):* With the infant supine, fully flex the forearm for 5 seconds, then fully extend by pulling the hands, and release; recoil time is graded *Prematurity:* Arm recoil—slow
Palm: No simian creases	Normal	I	*Definition:* Simian crease—a deep crease extending across the palm that results from the fusion of the two normally occurring horizontal palmar creases and is found especially in individuals with Down syndrome
Fingers: • 10 digits and without webbing • Equal spacing	Normal	I	
Carpals and metacarpals: • Present • Equal bilaterally	No fractures; bone formation normal	I	
Nails: Extend beyond nailbeds	Normal; full term	I	
Nailbeds: • Pink • Brisk capillary refill (< 3 seconds) • Equal bilaterally	Normal peripheral perfusion, normal oxygenation	Pa	

Upper Extremities			
Clavicles: Symmetrical Without fractures or pain	Normal	Pa	
Humerus, radius, and ulna: • Present • Symmetrical • Without fractures	Normal bone formation	Pa	
Pulses: • Brachial and radial strong and equal bilaterally • Brachial and radial strong and equal in comparison with femoral pulses	Good peripheral perfusion, without obvious cardiac defects	Pa	
Lower Extremities			
Legs: • Length in proportion to body • Equal bilaterally • Limbs straight	Normal extremity length	I	
Toes: • 10 digits • Without webbing • Equal spacing	Normal	I	
Feet: Straight	Normal	I	*Variations on normal:* • Valgus (turned outward) or varus (turned inward) position of the foot may be related to fetal position in utero and usually resolves • Pedal edema may be due to pressure exerted by fetal position in utero
Ankle dorsiflexion: 0-degree angle	Maturity	I	*Technique:* Foot is flexed back on ankle, then angle between foot and ankle is measured *Prematurity:* Ankle dorsiflexion angle $>$ 0 degrees; may be up to 90 degrees in very premature neonates
Popliteal angle: $<$ 90 degrees	Maturity	I	*Technique (NBS):* With the infant supine and the pelvis flat on the examining surface, the leg is flexed on the thigh and the thigh fully flexed using one hand; with the other hand, the leg is then extended *Prematurity:* Popliteal angle: $>$ 90 degrees and $<$ 180 degrees in very immature infant
Heel-to-ear maneuver	Maturity		*Technique (NBS):* With the infant supine, hold the infant's foot with one hand and move it as near to the head as possible without forcing it; keep the pelvis flat on the examining surface. The heel will not reach the ear but only near the shoulder area in a full-term infant. *Prematurity:* The heel reaches the ear, or just short of the ear
Nails: Extend to end of nailbed	Normal; maturity	I	*Prematurity:* Nails do not extend to end of nailbed

Lower Extremities			
Nailbeds: • Pink • Brisk capillary refill (< 3 seconds)	Good peripheral perfusion	I/Pa	
Plantar creases: Cover the sole of foot	Maturity	I	*Technique (NBS)*: With the infant supine and quiet, score as indicated on Figure 37-1 *Prematurity:* Plantar creases are few or cover only the anterior third of the sole of the foot
Buttocks: Creases symmetrical	Normal hips	I	
Fibula, tibia, trochanter, and femur: • Present • Equal bilaterally	No fractures; bone formation normal	Pa	
Tarsals and metatarsals: • Present • Equal bilaterally	No fractures; bone formation normal	Pa	
Full range of joint motion (includes abduction, adduction, internal and external rotation, flexion, and extension as applicable to respective joints of legs, knees, ankles, feet, and toes)	Normal; maturity	Pa	*Prematurity:* Limited range of joint motion; flexion of legs, knees, ankles, feet, and toes is limited
Hips: Without clicks and full range of joint motion	Normal range of joint motion and no clicks	Pa	*Technique*: Ortolani's maneuver—flex the newborn's hips and knees, then abduct and adduct the hip to detect a slipping of the hip out of the acetabulum or an uneven motion unilaterally *Technique:* Barlow's maneuver—flex the newborn's hips and knees, then place a finger on the femur and trochanter, put the hip through full range of joint motion, and listen for an audible click
Knee jerk or patellar reflex: • Present • Symmetrical	Normal; mature	Pa	*Prematurity:* Knee jerk or patellar reflex absent, weak, or asymmetrical
Flexor plantar reflex: • Present • Symmetrical	Normal; mature	Pa	*Technique:* Stroking the lateral part of the sole of the foot with a fairly sharp object produces plantar flexion of the big toe; often there is also flexion and adduction of the other toes *Prematurity:* Plantar reflex absent, weak, or asymmetrical
Extensor plantar (Babinski) reflex: • Present • Symmetrical	Normal; mature	Pa	*Technique:* When the sole of the foot is firmly stroked, the big toe extends (bends back toward the top of the foot) and the other toes fan out; this is a normal reflex up to about 2 years of age

Back			
Spinal column: Straight	Normal alignment	I	*Variation on normal*: A curved spinal column should gradually resolve if it results from fetal positioning while in utero
No visible deviations or defects	Intact	I	*Definition:* Pilonidal cysts—containing hair nested in a cyst; used to describe congenitally anomalous cysts in the sacrococcygeal area that often become infected and emit discharge through a channel near the anus
Vertebrae: Present, without enlargement or pain	Normal spinal column	Pa	
Anus: See genitourinary tract		Pa	
Buttocks: See lower extremities		Pa	

Abbreviations: A, auscultation; I, inspection; MOE, method of evaluation; NBS, New Ballard Scale; Pa, palpation; Pe, percussion; RBC, red blood cell.

Introduction

The role of the midwife in caring for the neonate during the first month of life varies markedly. In some locales, the midwife has little formal role once the newborn leaves the birthing room. In other practices, the midwife will continue care of the woman and newborn throughout the first several weeks of life. The *Core Competencies for Basic Midwifery Practice*, revised in 2012, states that certified nurse-midwives and certified midwives "independently manage the care of the newborn immediately after birth and continue to provide care to well newborns up to 28 days of life."[1] Regardless of the formal scope of practice in specific settings, parents often call their midwife with questions related to the care and well-being of their newborn. Thus, knowledge of normal newborn behaviors and signs of newborn disorders is an important component of practice for all midwives.

During the first hour after birth, a newborn must successfully navigate the physiologic transition from an intrauterine environment to an extrauterine one. This process is described in the *Anatomy and Physiology of the Newborn* chapter. A complete newborn examination is presented in the *Examination of the Newborn* chapter. This chapter reviews newborn care through the first month of life.

The First Golden Hour

The concept of the Golden Hour originated in the care of trauma victims, for whom the first 60 minutes of care tended to predict death or survival. Today this term can also be applied to the important hours and actions immediately after birth.[2]

The initial brief examination of the newborn is performed immediately after birth. Although it is not considered a formal physical examination, many important assessments are made during this evaluation that takes place in the first minute of life before a formal Apgar score is awarded. While the newborn is placed on the mother's abdomen or remains in the midwife's hands, the midwife focuses on identifying various neonatal parameters of health such as tone, color, and heartbeat (which can be palpated through touching the umbilical cord that has not been clamped and cut), as well as any obvious birth injuries or congenital abnormalities. In addition, physiologic responses of the newborn and corresponding parental behaviors are observed, all while maintaining vigilance regarding maternal well-being. Resuscitation is initiated if required, before the 1-minute Apgar score is given.

The second assessment is assignment of the Apgar score, preferably by someone other than the person conducting the birth so as to decrease bias. The Apgar score is discussed in more detail in the *Second Stage of Labor and Birth* chapter. Depending on the birth site guidelines or clinical indication, umbilical artery blood gases may be drawn. Also, if the parents have requested cord blood banking, it is obtained at this time.

Newborn Assessment and Care in the First Hours After Birth

In past decades, umbilical cords were immediately clamped and cut and the newborn was removed to a warmer, where professionals could perform immediate care measures, including a physical examination and assignment of the Apgar score. Several well-conducted studies have called into question the need for immediate evaluation and routine interventions with the newborn separated from the mother during the first hour after birth.[3]

Skin-to-Skin Contact

In lieu of separating mother and child, placing the newborn on the mother's abdomen provides several advantages. The newborn is dried while on the mother, and her warmth decreases neonatal chilling. Early skin-to-skin contact (SSC), also known as kangaroo care, promotes longer breastfeeding and has been found to result in less crying among newborns when compared to infants who are separated from their mothers immediately after birth.[4] Other potential advantages of SSC are purported to be related to the establishment of a trusting relationship between mother and child at a sensitive period, although long-term studies of the "sensitive period" hypothesis have not proved that SSC improves maternal–infant bonding over time.

Delayed Umbilical Cord-Clamping

Approximately 5 minutes after initial SSC is initiated, the umbilical cord is clamped and cut. Often the midwife performs this task, but the woman's partner or designated support person also may cut the cord between the two clamps. Waiting for at least 3 minutes to pass before clamping and cutting the cord—a practice known as delayed cord-clamping—allows for blood in the umbilical and placental circulation to be physiologically transfused to the newborn. Delayed cord-clamping is recommended for all newborns.[5-8] Although professional association guidelines have some differences, the evidence indicates a minimum of 3 to 5 minutes is optimal for the newborn.[8-12] The benefits and procedure for delayed cord-clamping are reviewed in the appendix to the *Second Stage of Labor and Birth* chapter.

Neonatal Hypothermia

Newborns are predisposed to developing hypothermia, as they have a large surface area per unit of body weight compared to adults. As discussed in the *Anatomy and Physiology of the Newborn* chapter, brown fat is the major site for production of heat and serves as the circulatory route for heat production, or nonshivering thermogenesis. Hypothermia is associated with depression of the central nervous system, hypoglycemia, metabolic acidosis, tachypnea, respiratory distress, and decreased peripheral perfusion. The newborn is at higher risk for hypothermia following hypoxic, hypoglycemic, or other stressful episodes.

Skin-to-skin contact provides the best source of heat for the newborn and can prevent

hypothermia.[4] SSC has also been found to be at least equal to incubators for rewarming infants who already have experienced chilling,[13] and has additional benefits in facilitating breastfeeding initiation.[4] **Table 38-1** lists other methods used to prevent hypothermia.

Table 38-1	Interventions to Prevent Newborn Hypothermia
Prewarm the newborn resuscitation area.	
Set the birth room temperature at 23.9°C (75°F).	
Prewarm any blankets, hats, or clothing prior to the birth.	
Place the newborn skin to skin on the mother immediately after birth.	
Gently dry the newborn after birth, and then immediately replace wet blankets with dry ones.	
Do not evaluate the newborn on wet sheets or towels.	
Postpone the newborn's bath until newborn temperature has been stable for 2 hours.	
Place the newborn care areas away from windows, outside walls, and doorways.	
Keep the newborn's head covered and body well wrapped.	

Maintaining the temperature of the birth room or operating room at 77°F (25°C) for term newborns and at 79–82°F (26–28°C) for preterm newborns is recommended by the World Health Organization (WHO).[14] Covering the newborn's head with a stockinet cap after initial drying is conventional care because the head has a large surface area from which heat can be lost; however, the cap may interfere with maternal–newborn odor recognition and the necessity of placing a cap on the newborn has not been proven. A warm, dry blanket tented over the newborn's head while the newborn is skin to skin with the mother will assist in thermostabilization.

The newborn's temperature can be assessed at various sites with different types of thermometers. Although historically rectal temperatures were commonly performed in newborns, this technique had disadvantages: The rectal temperature can remain high after the core temperature drops, it can be affected by the presence of stool, and rectal perforation is possible. Thus, rectal temperatures are no longer recommended. Axillary temperatures are normally in the range of 36.5–37.5°C (97.7–99.0°F) but may be falsely elevated in a cold-stressed infant secondary to metabolism of brown adipose tissue. Abdominal skin temperature is normally in the range of 36–36.5°C (96.8–97.7°F). Infrared tympanic thermometers (2 seconds in the ear) can be used to measure temperature but are likely the least reliable method for a newborn.

Noncontinuous temperature assessment will be accurate only if the thermometer remains in place for an adequate time. If temperature is assessed with an abdominal skin sensor, the sensor must be in good contact with the skin and covered with a reflective shield. Skin temperatures should be slightly lower than core temperatures.

Neonatal Hypoglycemia

In the first 2 hours post birth, a newborn's blood glucose level normally falls to a nadir of

approximately 40 mg/dL. In utero, the fetus has a continuous supply of glucose. Once outside the mother's body, the newborn must adapt to the change from this continuous supply to intermittent supply via breast milk. Blood glucose levels may remain slightly low for several days and the newborn will remain asymptomatic. Because there is a great deal of individual variability in blood glucose levels associated with clinical symptoms of hypoglycemia, no specific blood glucose value that defines hypoglycemia has been published.[15,16]

Despite the definitional controversy, newborns are at increased risk for hypoglycemia and specific risk factors have been identified. Newborns born to women who have diabetes, preterm infants, and newborns who are small for gestational age are at increased risk for hypoglycemia. Common symptoms of hypoglycemia include jitteriness, irritability, lethargy, or poor feeding. Blood glucose levels obtained by heel stick can be of value in diagnosing hypoglycemia. Any glucose value of 45 to 50 mg/dL or lower should be verified immediately via a venous sample, and the pediatric provider informed of the results.

Early and frequent feeding is an important preventive measure that protects most newborns from developing clinical hypoglycemia. The exact degree of hypoglycemia that requires formula feeding or intravenous glucose depends on other clinical factors such as feeding ability, weight, and risk factors for hypoglycemia.[17] Although hypoglycemia can be easily treated, in extreme circumstances prolonged hypoglycemia is associated with neurodevelopmental delays.

Evaluation of hypoglycemia is done via capillary blood sample. It is no longer recommended to warm the heel prior to sampling, as research has not revealed any benefit from heel warming with regard to blood flow, collection time, or newborn comfort.[18,19] When performing this blood test, care should be taken to avoid puncturing sensitive structures on the back of the heel (**Figure 38-1**).[18] Use of an automated blood collection device may cause less trauma and lead to more successful sample collection results than use of manual lancets and squeezing the heel, which creates hemolysis.[20] To prevent infection, the infant's heel should be cleansed with antiseptic, followed by sterile water, and allowed to air dry. Alcohol should be avoided, as it is drying and can leave residue. Newborn discomfort may be diminished by swaddling, being held in the arms of the neonate's mother or other family member, and non-nutritive sucking.[21]

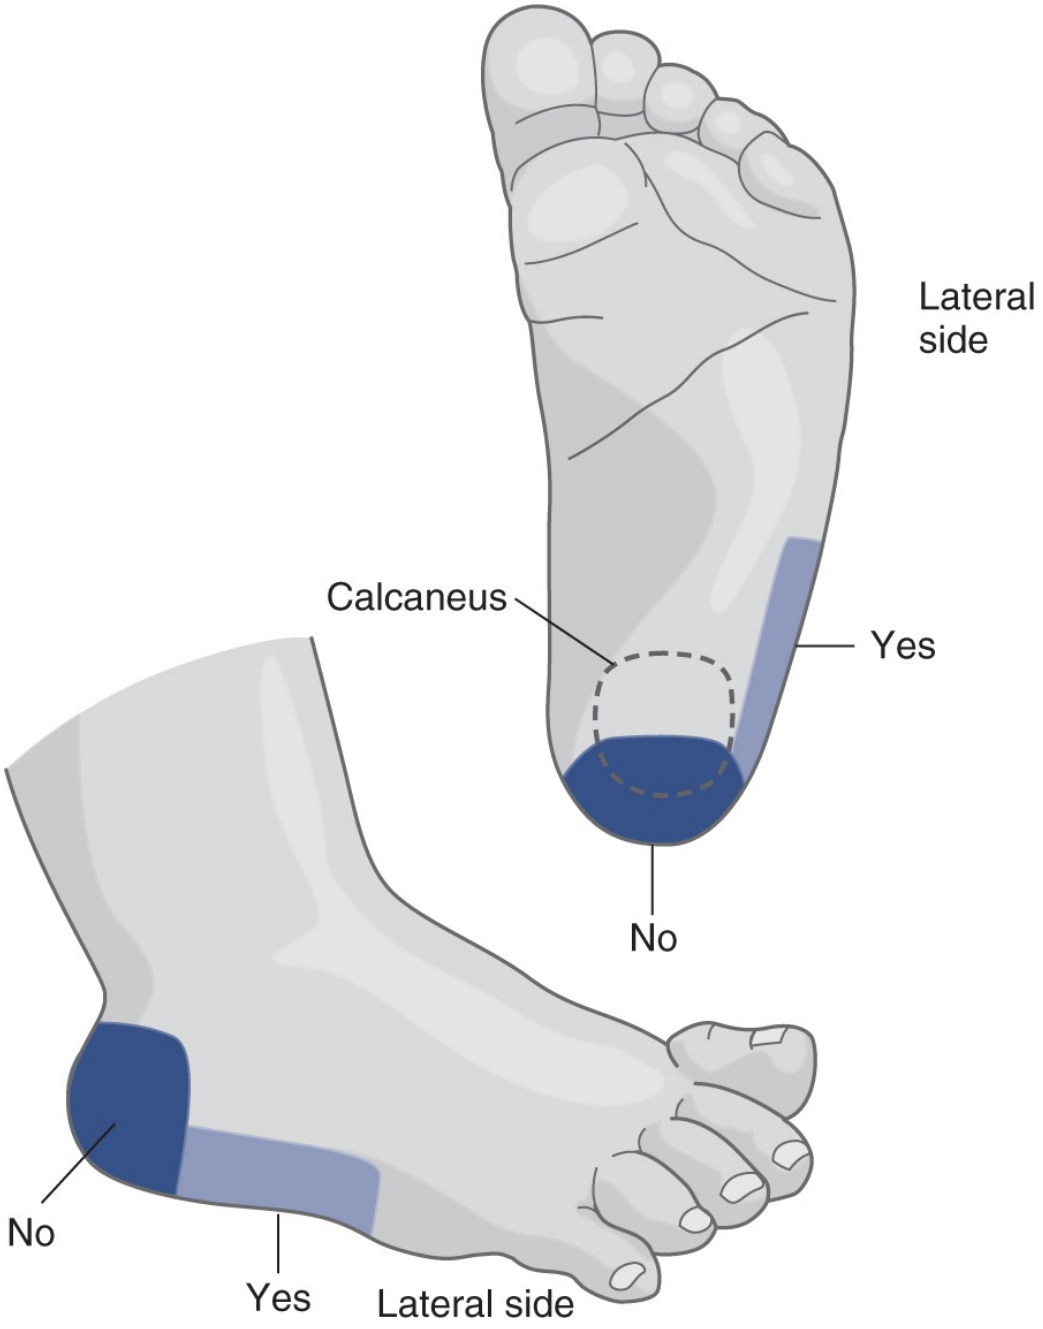

Figure 38-1 Anatomic landmarks for heel sticks.

Any glucose level below the recommended threshold for normal requires intervention. Feeding the infant is the first step. A repeat glucose test is performed 30 minutes after feeding and if the borderline level persists, a venous sample should be checked. Low values should be evaluated immediately with a venous sample drawn from a scalp vein or the antecubital fossa. If the low value is confirmed, pediatric consultation is needed and treatment is indicated.

Venous samples can be analyzed using either whole blood or plasma (serum). Samples should be chilled during transport to the laboratory. Most laboratories report the plasma result, which will be close to 15% higher than a sample run on whole blood. Thus, it is important to know the testing method and reference ranges used by a particular lab to accurately interpret the test results.

Initial Newborn Prophylaxis Treatments

Two prophylactic treatments are recommended for newborns within the first 4 hours of life: ophthalmic treatment for prevention of ophthalmia neonatorum and administration of vitamin K to prevent hemorrhagic disease of the newborn.

Ophthalmic Treatments

Eye prophylaxis is pharmacologic treatment originally intended to prevent blindness associated with undiagnosed maternal *Neisseria gonorrhoeae* infection. Today in the United States, neonatal conjunctivitis (also known as ophthalmia neonatorum) is more commonly caused by the *Chlamydia trachomatis* organism. Maternal screening and treatment during pregnancy is the first step in prevention of blindness caused by chlamydia or gonorrhea, but does not guarantee that reinfection has not occurred at the time of birth.[22]

The risk that the infant will acquire conjunctivitis is 20% to 50% if a woman is infected when she gives birth. Neonatal conjunctivitis secondary to *C. trachomatis* infection usually becomes symptomatic 5 to 14 days after birth.[22] Conjunctivitis secondary to *N. gonorrhoeae* infection becomes symptomatic 1 to 5 days after birth; the risk that the infant will acquire conjunctivitis is 30% to 40% when the mother has gonorrhea.

In years past, silver nitrate or tetracyclines were employed as treatments to prevent colonization from causing conjunctivitis or blindness. Today, erythromycin 0.5% ophthalmic ointment is the Centers for Disease Control and Prevention (CDC) recommendation for neonatal ocular prophylaxis throughout the United States. Its effectiveness against *N. gonorrhoeae* is proven, and this medication is considered the only available prophylaxis against *C. trachomatis* conjunctivitis.[22] Infants may develop a chemical conjunctivitis after eye prophylaxis, but that condition resolves spontaneously within 24 to 48 hours. In low-resource countries, small studies of the use of povidone–iodine eventually may provide an alternative treatment.[22]

The medication should be applied within 2 hours after birth. Some legal jurisdictions mandate that the eye prophylaxis be performed within the first hour of life, but in those situations many professionals wait until the end of the hour to apply this treatment so as to promote better *en face* interactions between parents and newborns. The medication is placed on each of the lower conjunctival sacs and spread with gentle massage of the eyelids. The excess ointment can be wiped away after 1 minute, but the eyes should not be irrigated.

Prophylactic Administration of Vitamin K

Newborns do not have a major store of vitamin K. In addition, the levels of vitamin K are low in breast milk, and the neonate’s gut flora, which usually includes bacteria that produce vitamin K, tends to be immature. A deficiency of this vitamin can result in the condition termed hemorrhagic disease of the newborn (HDN) or vitamin K–deficiency bleeding (VKDB).

HDN commonly is categorized as either early (within 24 hours of life), classic (days 1–7), or late (2–12 weeks). Early HDN is rare and requires immediate pediatric consultation when the infant is bleeding, especially from injection sites or the umbilicus. Early HDN is most

commonly found among infants whose mothers have taken pharmacologic agents such as anticonvulsant drugs. Classic HDN is most commonly found among infants who have not received prophylactic vitamin K injection during the first day of life, with the most common bleeding sites being gastrointestinal, cutaneous, or penile (subsequent to a circumcision). Late HDN is most common among newborns who are being exclusively breastfed and have not received prophylaxis; it is potentially the most serious type of vitamin K deficiency, as many infants affected with this variation develop intracranial bleeding.

A single injection of vitamin K, 1.0 mg given intramuscularly, has been found to prevent classic HDN.[23] For exclusively breastfed infants, the intramuscular injection also is protective, although some evidence suggests that an oral administration of 1 mg vitamin K may be effective as well.[24] Controversy exists regarding the best route of administration for prophylaxis of infants at risk of late HDN. Intramuscular injection appears effective and is the only Food and Drug Administration (FDA)–approved route, whereas the single oral dose may be subtherapeutic.[25]

The First Hours: The Newborn with an Unexpected Immediate Health Condition

Prenatal assessments of fetal morphology do not detect all congenital anomalies. When a newborn presents with an unexpected health problem, the midwife identifies deviations from normal and initiates transfer to pediatric care. A critical component of this process is communicating the degree of urgency and the midwife's assessment of how quickly pediatric assistance is needed.

Congenital Defects

Some anomalies, such as cleft lip and extra digits can be surgically corrected without long-term sequelae. Other types of congenital defects can result in rapid deterioration in the newborn and may lead to significant morbidity and mortality if not properly managed. Of these, abdominal wall defects and spinal cord defects pose particular challenges.

Abdominal wall defects are subdivided into gastroschisis and omphalocele, both of which have unclear etiologies.[26] *Gastroschisis* is a condition in which the eviscerated abdominal organs are not covered by a peritoneal membrane sac. In an *omphalocele*, the abdominal organs are external but are covered by peritoneal membrane that protects the intestines from exposure to amniotic fluid and, after birth, ambient air. In both cases, there is a high likelihood of infection, hypothermia, and dehydration because of the large surface area that is exposed.

Management of the newborn with an abdominal wall defect requires an immediate call for pediatric assistance and transport to a tertiary pediatric hospital or unit. The newborn is placed in a radiant warmer in as sterile an environment as possible. Sterile, warmed saline is applied to the eviscerated abdominal contents via sterile gauze pads. The infant's torso is then wrapped in sterile gauze to keep the saline in place. The infant is not fed via breast or a bottle; instead, a feeding tube is inserted and any stomach contents are aspirated. This neonate has an acute need for intravenous fluids.

The two most common neural tube defects are meningocele and meningomyelocele (also called spina bifida).[27] *Meningocele* is a bony defect of the spinal cord. With *meningomyelocele*, the vertebra is defective and the spinal cord and spinal roots are externally located in a meningeal sac. Meningomyeloceles are usually found in the lower spine, lumbar, and sacral areas. The principles for immediate management of spinal cord defects are similar to those described for abdominal wall defects: application of a sterile, warm saline dressing with a dry sterile overwrap; thermoregulation; and fluid maintenance. In addition, the infant is positioned prone and fecal contamination is scrupulously avoided.

Diaphragmatic hernias are surgical emergencies in the newborn because herniation of abdominal contents into the chest cavity may have caused pulmonary hypoplasia.[28] These hernias are usually unilateral on the left. The degree of respiratory distress is directly related to the amount of lung tissue that has been compromised. In some newborns, the herniation is so severe that there has been stunted, if any, lung growth on the affected side. Signs of diaphragmatic hernia include decreased left-sided breath sounds, heart sounds on the right side, and severe respiratory distress at birth secondary to persistent pulmonary hypertension.

Depending on the degree of the defect, the abdominal contents may be in the chest cavity, which causes a concave (scaphoid) abdominal contour. Skilled pediatric care must be sought immediately.

Birth Injuries

Palsies and plexus conditions generally are categorized as birth injuries and traditionally have been assumed to be associated with an event such as shoulder dystocia. Nevertheless, injury may sometimes occur in utero, such that parents and professionals are surprised when the child is born with a palsy or injury after an uneventful labor and birth.[29,30]

Facial Palsy and Brachial Plexus Injuries

Injuries to the face include bruising from forceps or facial palsy caused by either forceps or pressure from the maternal sacrum. Consultation may be needed, and use of an eye patch and lubricating eye drops are common treatments. Injuries to the brachial plexus may occur prenatally or during a birth when traction is applied to the neck.[30] Such injuries can occur during breech births, during births involving shoulder dystocia, or following an operative vaginal birth.

Management includes referral for splinting of the affected arm close to the body and consultation with the pediatric team. Parents are encouraged to minimize handling the affected extremity for the first week because of the pain involved. Parents can be reassured that in the vast majority of newborns, paralysis disappears in 3 to 6 months, with initial improvement becoming evident within a few weeks. Physical therapy is helpful after the first swelling subsides.

Injuries to nerve roots higher in the brachial plexus (C3–C5) can cause signs of significant respiratory compromise because of paralysis of the phrenic nerve and diaphragmatic compromise.[30] Newborns with this type of nerve injury take very shallow breaths with limited respiratory excursion and need aggressive respiratory support after birth. When injuries do not respond to 6 months of physical therapy, surgical repairs are often attempted.

Bone Fractures

Management of bone fractures includes obtaining a pediatric consultation and splinting. If a clavicle or arm fracture is suspected, parents can be assured that newborn bones usually heal well and quickly.

Cephalohematoma, Subgaleal Hemorrhage, Intracranial Hemorrhage, and Skull Fractures

Injuries to the head include cephalohematoma, subgaleal hematoma, intracranial hemorrhage, scalp abrasions, retinal hemorrhage, and skull fractures.[31] Cephalohematomas and small scalp abrasions occur in approximately 10% of newborns who are delivered by vacuum extraction.[31] Cephalohematomas can also occur during a spontaneous vaginal birth, although the incidence

of such injuries is much lower. More severe cranial hemorrhages are more often associated with forceps deliveries.

Pediatric support is needed urgently if symptoms of a subgaleal hemorrhage are present. Symptoms of intracranial hemorrhage generally appear a few hours after birth and include irritability, apnea, poor feeding, or lethargy, and possibly a bulging fontanel.

A clear sign of a skull fracture is a depressed area of fetal skull, particularly over the parietal bones. An area of skull depression increases the possibility that fragments of skull bone have penetrated through the dura, the covering of the brain. Management includes careful positioning of the newborn on the side opposite the affected area and consultation with the pediatric team, who will order imaging tests.

The First Golden Days: Normal Newborn Behavior

Parental advice from professionals, websites, social media, and even family often assumes that all newborns act similarly. In reality, each neonate is an individual—and all information, especially about behavior, should be viewed in that light. The midwife can help parents develop realistic expectations about normal newborn behavior during the newborn period. If this is the only aspect of newborn care in which the midwife is involved, it can be one of the most important and significant contributions offered by a healthcare professional to the new family in the first several weeks postpartum.

Sleep and Wake States

Newborns are in a period of behavioral instability. By the time parents figure out a pattern of newborn behavior, that pattern will have changed. A good rule of thumb for the first month of life is "There is no pattern."

Newborns' activities fall into two major categories of behavior: periods of waking and periods of sleeping. The waking states include crying, considerable motor activity, alert, and drowsy. The sleep states include active (light) sleep and deep sleep. **Table 38-2** summarizes these states, along with their implications for care.[32,33]

Table 38-2 **Infant Behavioral States**

State	Appearance	Eye/Facial Movements	Breathing	Response to Stimuli	Implications
Sleep States					
Quiet sleep (deep sleep)	Essentially still with occasional startle	Occasional regular sucking, otherwise still	Smooth and regular	Tolerates stimuli well; only responds to intense stimuli	Avoid trying to feed at this time; will lead to frustration
Active sleep (light sleep/REM sleep)	Some body movements	REM Fluttering of eyes with occasional smiling or crying sounds	Irregular	More responsive to hunger and handling than in quiet sleep; if stimulated, may return to active sleep to progress to quiet sleep or arousal	Highest proportion of newborn sleep Usually occurs before arousal Although may provide evidence of hunger, will not eat well in this state
Awake States					
Drowsy	Activity varies	Eyes may open and close or be slit-like in appearance Although often no facial movement, may have some smiling or sounds	Irregular	Will respond to stimuli, although response may be delayed	To promote awakening, provide some stimulation such as visual, auditory, or sucking stimulus
Quiet alert	Minimal movements	Eyes widen Face appears bright and attentive	Regular	Very responsive	Often occurs immediately after nonmedicated birth and can be positive for parent–child interactions As baby ages, spends more time in this state Good state in which to feed baby
Active alert	Smooth movements but variable activity	Eyes are open, but appearance is more dull Although often no facial movement, may have some smiling or sounds	Irregular	Will respond to stimuli, although response may be delayed	More sensitive to stimuli (e.g., hunger, handling) May move into crying state If fatigued, may move into drowsy or sleep state
Crying	Increased body movements, often with darkening skin tones	Eyes may be open or closed Grimaces	More irregular than other states	Very responsive, especially to negative stimuli	Sometimes crying infants can self-console May need swaddling, cuddling, or other measures to resolve crying

Abbreviation: REM, rapid eye movement.

Based on Blackburn S, Bakewell-Sachs S. *Understanding the Behavior of Term Infants.* White Plains, NY: March of Dimes Birth Defects Foundation. Available at: http://www.marchofdimes.com/nursing/modnemedia/othermedia/states.pdf. Accessed July 12, 2017.[33]

During the first month of life, the percentage of time spent in each of these states changes. Healthy newborns spend as much as 60% of their time sleeping. However, much of this sleeping takes the form of short naps. As the first month of life progresses, infants shift away from active (light) sleep and toward more extended periods of deep sleep. Similarly, there is a shift in the waking states toward an increase in alertness.

Newborn Reflexes

The newborn has two categories of reflexes: *proprioceptive* and *exteroceptive*. The proprioceptive reflexes include gross motor reflexes such as the Moro reflex, which can be checked at any time. Complete absence of any of these reflexes is a cause for alarm. The exteroceptive reflexes are best evoked when the infant is quiet and alert, as they are stimulated by light touch. They include the rooting, grasping, plantar, and superficial abdominal reflexes. An incomplete elicitation of a reflex may occur in some circumstances—for example, with neurologic depression secondary to medication. The loss of a previously strong reflex in the first month of life is a cause for alarm and must be reported promptly to a pediatric provider.

Sensory Capabilities

Sensory capabilities are strongly related to gestational age. Dramatic increases in the sensory stimulation that occur just after birth can lead to neonatal exhaustion, evidenced as fussiness or

aversion. Crying infants and fatigued mothers are frequently associated.[32]

At term, the healthy newborn has an ability to fix on and track objects visually. Many studies have shown a strong newborn preference for patterns of stripes. During the first month of life, however, newborns become preferentially interested in patterns with contours that resemble the human face. The ability to see in color is limited at first, so newborns respond well to black-and-white patterns or strong colors like red. Newborns in the alert behavioral state will spend some minutes staring at patterns.

The newborn has the ability to discriminate among distinctive odors.[34] A newborn can discriminate between the odor of the mother's breast pad and the odors of the breast pads of other nursing women. Newborns react strongly to variations in taste and show a strong preference for sweet liquids. They suck longer and with an increase in heart rate when presented with a sweet liquid in a bottle.

Newborns also have acute hearing and are able to localize sound in the environment. They can discriminate finely among sounds and show a preference for real voices as opposed to synthesized voices. By the end of 1 month, neonates prefer sound with a pattern similar to speech.

Prior to birth, the fetus experienced touch in the form of the shifting amniotic fluid. At birth, the newborn is dry for the first time and is subject to many and varied forms of touch. The ability of the newborn to respond to touch is well demonstrated with the elicitation of the various exteroceptive reflexes such as rooting, grasping, abdominal reflexes, and spinal curving.

Regulation of Behavior

Infants may convey their ability or inability to engage by a variety of neurobehavioral cues. For example, stability and engagement cues include sucking, smiling, feeding posture, flexion of arms and legs, searching for a sound, and facial eye-to-eye contact and normal vital signs. Distress cues include behaviors such as crying, grimace, startle or jerky movements, changes in skin color and turgor, grunting, arching, tachypnea or bradycardia, jitteriness, flaccidity or tremors, and vomiting, frequent regurgitation, or stooling.[35]

Caregivers play a critical role in infant brain development by interacting and helping the infant regulate the stress response system. The caregiver interprets behavioral cues and responds with visual, vocal, and physical interactions that provide feedback to the infant. Each infant has a unique ability to react to stimulation presented by the environment and personal bodily functions. Infants vary in their responses to these stimuli. The newborn learns best in the alert state.

On occasion, a midwife may recommend to parents that the Brazelton Neonatal Behavioral Assessment Scale (NBAS) be performed.[36] This test generates a picture of the infant's communication via responses to stimuli and neurologic reflexes. The results are used to help parents interpret their newborn's behaviors. The test is standardized and can be reliably administered only by a trained examiner. The NBAS begins with the newborn in a sleeping state. Repeated stimulations are offered, and the examiner observes how the newborn adjusts to the stimuli. The behavioral components of the NBAS assess the infant's ability to perform

the six tasks listed in **Table 38-3**.[36]

Table 38-3	Behavioral Components of the Brazelton Neonatal Behavioral Assessment Scale
Organization of behavioral state	
Decrease in motor activity in an attempt to cope with sensory input	
Ability to become alert and oriented to auditory and visual stimuli	
Interaction with a caregiver through cuddling	
Ability for self-consoling	
Habituation to repeated stimulation	

Based on Brazelton TB, Nugent JK. *Neonatal Behavioral Assessment Scale*. 4th ed. London, UK: Mac Keith Press; 2011.[36]

Several other assessment instruments also address infant behaviors and development. For example, the Denver Developmental Screening Test (Denver Scale) assesses children from birth to age 6 years. Similar to the NBAS, this test observes the actions of the child and can assist in identifying conditions suggestive of cerebral palsy. The Broussard Neonatal Perception Inventory explores how mothers perceive their infants and assesses the attachment of the mother to child.[37] A number of other assessment tests exist, but most—if not all—cannot be used as diagnostic instruments.

Psychological Tasks of Early Infancy

During the first months after birth, a profound psychodynamic develops between the infant and the principal caregiver (usually the mother). The infant is performing the psychological task differentiation: identifying as a separate being in relation to other beings. A growing body of research implicates the maternal hormone oxytocin in the initiation and maintenance of human attachment behaviors.[38] The brain is a target organ for oxytocin activity, as it is known to contain oxytocin receptors.

Although most of the literature refers to maternal–infant attachment, it is important to be cognizant of other possible “secure bases” for infants, including fathers, grandparents, or others who become primary caregivers. In discussions with the newborn’s primary caregivers, the midwife can explain the critical importance of response to infant cues.

The First Golden Days of Life: Care of the Healthy Neonate

Breastfeeding

The *Breastfeeding and the Mother–Newborn Dyad* chapter provides an overview of the evidence in favor of the importance of establishing early breastfeeding. The mother–newborn dyad is supported with knowledgeable assistance, especially during the early days when lactation is initiated and learned by both mother and newborn.

Newborn Bathing

WHO recommends delaying bathing for a minimum of 6 hours after immediate drying to prevent hypothermia and to facilitate skin-to-skin warming and early breastfeeding.[39] Several studies have found that water alone is as effective as mild soaps in cleansing infants.[40] Antimicrobial soaps tend to be harsh and are to be avoided.[41] Currently, more rigorous dermatologic studies are needed to clarify the effects that the various bathing methods have on neonatal skin integrity and hydration.[41]

Cord Treatments

In years past, treatment of the umbilical cord stump was initiated immediately or shortly after birth. Various antiseptic solutions were used, including rubbing alcohol, iodine, goldenseal, and echinacea. Today, the prevailing advice is to simply keep the area dry. A Cochrane systematic review found that newborns with cords treated with antiseptic solutions were no more or less likely to develop omphalitis when compared to neonates who received no treatment or placebo.[42] Conversely, some evidence suggests that treatment with an antiseptic solution may prolong adherence of the cord.

The Cochrane review was primarily based on studies in developed nations where births occurred in clean conditions. Few studies have explored treatments in low-resource settings where newborns frequently die from such conditions as neonatal tetanus; however, WHO recommends chlorhexidine as a cord treatment following birth in locations with poor sanitation. In those areas, additional research is needed, especially regarding the potential advantages of antiseptic solutions used to treat the umbilical cord stump.[42]

Newborn Screening and Vaccination

Technological developments in the last 60 years have increased the ability to screen newborns for diseases and conditions that are life threatening but not apparent at birth.[43-49] Routine newborn screening began in the 1960s when it became possible to detect phenylketonuria (PKU). Today newborn screening programs test for a wide variety of conditions.

Most newborn screening tests are mandated in all states within the United States. The states run the newborn screening programs, however, so there are some differences between states in

which tests are included in the screening program. The U.S. Department of Health and Human Services has published a list of tests that are recommended to be included in all state programs. Information about the Recommended Uniform Screening Panel Core Conditions and those included in the state programs can be found in the Resources section at the end of this chapter.

Parental education may be included in the state newborn screening programs; however, in some states, midwives may not be reimbursed for providing this type of health education. Some states mandate testing of only newborns who are born in hospitals and do not address neonates born in out-of-hospital settings. Midwives who practice in out-of-hospital settings may either invest in the appropriate equipment for newborn screening or refer new parents to facilities wherein they can obtain the necessary screening.

There is a general consensus that no test should be included in a state newborn screening program unless treatments—albeit not necessarily "cures"—exist.[49] Factors such as financial and family costs of false-positive results have been discussed as important considerations when a particular test is being evaluated for inclusion in a state program. Privacy of the newborn's genetic material also has been noted as a concern.[49,50]

Point-of-Care Testing

Newborn screening has expanded to include hearing tests and pulse oximetry to detect cardiac conditions. As opposed to dried-blood testing that is performed in a central laboratory, hearing tests and pulse oximetry are performed and interpreted outside of a laboratory and at, or close, to the site of direct care. This type of screening is also known as point-of-care testing.[50]

Hearing Testing

In the United States, universal hearing screening is advocated for all infants younger than the age of 1 month.[51] Approximately half of children with hearing loss have no identifiable risk factors; thus, risk-based screening for these problems has been problematic. Universal hearing screening has been found to be useful and newborns with hearing conditions identified in this manner have benefited from early intervention and ultimately fewer communication disorders.[52]

Hearing programs often follow a two-step process, beginning with otoacoustic emissions (OAE) testing in the first few days of life. If a newborn fails the OAE test, an auditory brain stem response (ABR) is conducted. In some sites, both tests are regularly performed. False-positive results occur occasionally, so confirmatory testing by pediatric providers is necessary. Midwives who conduct out-of-hospital births may find the equipment needed for such testing and its maintenance to be costly. In such a case, they may instead refer parents to sites such as hospitals that will administer the testing.

Pulse Oximetry for Congenital Heart Defects

Although a number of studies in the early twenty-first century found that pulse oximetry is a

good screening method to identify undiagnosed critical congenital heart defects (CCHDs) among otherwise healthy newborns, the initial research had few participants and a low prevalence of CCHDs.[53,54] However, by 2013, a systematic review of almost 250,000 infants found that the screening is highly specific, moderately sensitive, and likely to be cost-effective.[55]

Pulse oximetry screens for several major and secondary CCHDs, including hypoplastic left heart syndrome, pulmonary atresia with intact septum, tetralogy of Fallot, coarctation of the aorta, and transposition of the great vessels. In the normal newborn, oxygenation should be higher than 95%. Less than a 3% difference should be apparent when the pulse oximetry results for the foot and results for the hand are compared. As with hearing testing, midwives who conduct out-of-hospital births may need to find alternative sites that will perform pulse oximetry testing.

Hepatitis B Vaccine

Vaccination of the newborn against hepatitis B within the first 12 hours of life has been recommended in the United States for more than 30 years. The schedule for hepatitis B immunization of a newborn/infant varies based on maternal status. With mothers who are positive for hepatitis B surface antigen (HBsAg), the infant receives both hepatitis B vaccine (HBV) and hepatitis B immune globulin (HBIG) within the first 12 hours of birth.[56] These injections are administered in separate sites. Although the majority of states have laws requiring obstetric providers to screen women for hepatitis B, occasionally a woman presents for care and her HBsAg status is unknown. Neonates born to these women should receive HBV within the first 12 hours of life, and maternal blood should be tested as soon as possible. If the maternal HBsAg test is positive, HBIG should be immediately administered to the newborn within the first week of life.[56]

For several decades, the Centers for Disease Control and Prevention (CDC) has recommended that all newborns be immunized against hepatitis B.[56] Although there is some controversy about the need for the HBV for this age group, seroprotection following the vaccine's administration has been confirmed.[57] The current recommendation is that all infants receive the first dose of HBV within 12 hours of birth. **Table 38-4** summarizes the CDC recommendation based on whether the mother has a negative, positive, or unknown HBsAg test.[56] According to the CDC, licensed vaccines contain 10 to 40 mcg of HBsAg protein per milliliter; they do not contain thimerosal. Only a single-antigen HBV is used for the birth dose.

Table 38-4 Hepatitis B Vaccine Schedules for Term Newborn Infants, by Maternal Hepatitis B Surface Antigen Status

Single-Antigen Vaccine		Single-Antigen + Combination Vaccine	
Dose	**Age**	**Dose**	**Age**
Maternal HBsAg Positive			
1[a]	Birth (≤ 12 hrs)	1[a]	Birth (≤ 12 hrs)
HBIG[b]	Birth (≤ 12 hrs)	HBIG	Birth (≤ 12 hrs)
2	1–2 months	2	2 months
3	6 months	3	4 months
		4[c]	6 months (Pediarix) or 12–15 months (Comvax)
Maternal HBsAg Unknown[d]			
1[a]	Birth (≤ 12 hrs)	1[a]	Birth (≤ 12 hrs)
2	1–2 months	2	2 months
3[c]	6 months	3	4 months
		4[c]	6 months (Pediarix) or 12–15 months (Comvax)
Maternal HBsAg Negative			
1[a,e]	Birth (before discharge)	1[a,e]	Birth (before discharge)
2	1–2 months	2	2 months
3[c]	6 months	3	4 months
		4[c]	6 months (Pediarix) or 12–15 months (Comvax)

Abbreviations: HBIG, hepatitis B immune globulin; HBsAg, hepatitis B surface antigen.

[a] Recombivax HB or Engerix-B should be used for the birth dose. Comvax and Pediarix cannot be administered at birth or before age 6 weeks.
[b] Hepatitis B immune globulin (0.5 mL) is administered intramuscularly in a separate site from the vaccine.
[c] The final dose in the vaccine series should not be administered before age 24 weeks (164 days).
[d] Mothers should have blood drawn and tested for HBsAg as soon as possible after admission for delivery; if the mother is found to be HBsAg positive, the infant should receive HBIG as soon as possible but no later than 7 days of age.
[e] On a case-by-case basis and only in rare circumstances, the first dose may be delayed until after hospital discharge for an infant who weighs 2000 g or more and whose mother is HBsAg negative. When such a decision is made, an order to withhold the birth dose and a copy of the original laboratory report indicating that the mother was HBsAg negative during this pregnancy should be placed in the infant's medical record.

Reproduced with permission from Mast EE, Margolis HS, Fiore AE, et al.; Advisory Committee on Immunization Practices. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: recommendations of the Advisory Committee on Immunization Practices (ACIP). Part 1: immunization of infants, children, and adolescents. *MMWR Recomm Rep*. 2005;54(RR-16):1-31.[56]

The HBV series consists of either three or four injections, based on the type of HBV employed. In some parts of the world, a combination vaccine including vaccination against hepatitis B, diphtheria, tetanus, pertussis, and influenza is administered during the first year of life.[58]

Some parents decline HBV for their infants. This decision reflects maternal autonomy, although evidence supports the advantages of primary prevention of disease through immunization, as discussed in the *Health Promotion Across the Lifespan* chapter. However, for women who are HBsAg positive, there are distinct risks to the infant regarding development of chronic hepatitis B and potentially fatal hepatic carcinoma or cirrhosis. Thus, the ethical concerns in such situations are more complex, and the family can be best served with a full discussion of the risks and benefits associated with the disease and with vaccination.[59]

Circumcision

In the United States, circumcising male newborns became prevalent in the 1950s. A complex set of religious, cultural, and family traditions are contributed to the decision about circumcision. The type of practitioner who performs a circumcision varies. In many sites, the obstetrician is the clinician responsible for this procedure, while in other areas it is a pediatric provider or a family physician. If the reason for the procedure is religious, a cleric such as a rabbi or a midwife who also is a Mohel may perform the circumcision. Circumcision is not a core competency in midwifery education, but midwives practicing in the United States can learn and offer this procedure as an advanced procedure following the recommended steps outlined in the *ACNM Standards for the Practice of Midwifery*.

The circumcision procedure involves the surgical removal of adhesions and retraction of the foreskin covering the glans of the penis (prepuce). This procedure usually occurs in the hospital or within the first two weeks of life as a religious ceremony. Anesthesia is indicated for the newborn. Complications from circumcision are unusual but can be serious, with the most common being infection and bleeding. Although the foreskin of male newborns is rarely able to be retracted, within the first few years the foreskin can be spontaneously retracted for the vast majority of male children who are not circumcised.

The contemporary rationale for circumcision is a source of controversy. Arguments exist both for and against male circumcision, although true benefits and hazards are relatively rarely cited.[60] Proponents of circumcision note that circumcised males experience lower incidence of medical problems including cancer of the penis, urinary tract infection (UTI), and sexually transmitted infection (STI). Cancer of the penis is an unusual malignancy, especially in the cooler climates of the Northern Hemisphere. UTIs are similarly uncommon in infants. A number of studies have found a positive correlation between men who were uncircumcised and increased incidence of STIs, including human immunodeficiency virus (HIV), although other contributing factors such as socioeconomic class and sexual practices have clouded the association, especially in developed countries. Routinely circumcising newborns does prevent the small percentage of men with phimosis (inability to retract the foreskin) from developing problems with edema and inflammation of the glans, and male circumcision does not interfere with reproductive function of the penis.[61]

For some, this topic inspires passionate debate, in which male circumcision is likened to female circumcision or genital mutilation. Opponents of circumcision maintain that modern sanitary conditions in the United States diminish the need for this procedure and argue that the procedure is a painful violation of a nonconsenting infant that removes a functional body part. Parents who choose not to circumcise their sons are taught the normal anatomy of the penis and its development. As the child matures, he will be taught to retract the foreskin gently while bathing to clear any collection of smegma. Parents are counseled not to retract a foreskin forcefully, as the resultant irritation and edema may cause further adhesions.

Just as conflicting opinions have arisen in the general population regarding circumcision, so the American Academy of Pediatrics (AAP) has issued statements on this practice that have varied over the years. Based on research studies from 2005 to 2010, the most recent AAP statement notes that the health benefits of circumcision outweigh the risks and supports access

to the process for families who choose it.[61,62] A critical component of this statement is the informed desire of families. Information about circumcision is included in prenatal care, giving women and their families adequate time to make this decision. Some practices develop their own culturally sensitive documents to help individuals with this decision-making process.

Maternal Conditions That Influence Newborn Care

Women with HIV

HIV infection is a major perinatal threat. In the late 1990s, a major breakthrough occurred when a study found that treatment of newborns born to HIV-positive mothers with zidovudine (AZT, Retrovir) reduced the infants' risk of developing the infection.[63] In 2013, it was reported that a newborn with evidence of HIV shortly after birth was treated with a short course of multiple antiviral agents and later was found to be free of any infection.[64] Today, treatment of newborns born to women with HIV is recommended, but the appropriate drug, dosing, and follow-up have yet to be codified. A newborn whose mother has HIV is best treated by a pediatric provider with expertise in this area.

In the United States, it is recommended that HIV-positive women not breastfeed their infants because the virus is transmitted through breast milk. However, in areas where safe breast milk substitutes are lacking, the risks of HIV must be weighed against the risks of newborn diarrhea and nutritional deficits associated with bottle feeding; thus, the recommendation to breastfeed or not is a more complex decision in such locations.[65]

Colonization with Group B *Streptococcus*

Group B *Streptococcus* (GBS) infection is a leading cause of neonatal sepsis in the United States.[66] Approximately 1 in 100 to 200 newborns born to women who are colonized with GBS will develop newborn sepsis if the woman is not treated in labor. Because newborn sepsis has a significant risk of morbidity and mortality, efforts to prevent GBS-related newborn disease have been a standard part of maternity care in the United States since 1996.

The term infant whose mother received thorough intrapartum GBS prophylaxis—defined as 4 hours or more of penicillin, ampicillin (Principen), or cefazolin (Ancef) during labor in the hours immediately before the birth—should be observed for 24 to 48 hours; nevertheless, these newborns do not require special diagnostic testing unless they have signs or symptoms of illness.[67] Conversely, all infants who have signs of sepsis and all infants whose mothers have developed chorioamnionitis should have an evaluation and antimicrobial therapy. The 2010 algorithm published by the CDC can be found on their website. It is anticipated that the algorithm for neonatal care of newborns exposed to GBS will be updated in 2018 by the American Academy of Pediatrics.

Women with Diabetes

Women who have diabetes are at increased risk for having newborns with low or high birth weight, congenital anomalies, birth injuries, polycythemia, and hypoglycemia.[68] Newborns who are born to women who have diabetes may be either macrosomic or growth restricted, depending on the type and severity of the woman's diabetes. Newborn hypoglycemia may result from hyperinsulinemia that developed in response to intrauterine hyperglycemia from exogenous maternal glucose and diminished endogenous glucose production. This condition is

temporary for the newborn. Hypoglycemia is less common if the woman managed her diabetes well during pregnancy and had stable blood glucose levels.

Because of the risk of hypoglycemia, early feeding is important for these newborns. A blood glucose level should be obtained from these newborns during the first 2 hours of life.[69] A consultation with a member of the pediatric team is needed if any abnormal blood glucose levels are reported because intravenous fluids may be indicated.

Maternal Substance Use

The term *drug exposure*, when used in reference to a newborn, covers a wide variety of substances and situations. Many attempts have been made to quantify the effects of exposure on the fetus and newborn following in utero exposure to substances such as nicotine, alcohol, and illicit drugs. One major limitation of many of these studies is that many women who use drugs may be polydrug users. In addition, drugs of abuse often vary in terms of their additives and purity. Women who use drugs also may suffer from malnutrition, poverty, and chronic stress that can have an independent adverse effect on the fetus/newborn.

Newborns who have had significant exposure to a teratogenic or fetotoxic agent during pregnancy frequently will be small for gestational age and may have dysmorphic physical characteristics. Neonatal withdrawal symptoms include a wide spectrum of physiologic and neurobehavioral symptoms. Any infant suspected of being at risk for neonatal abstinence syndrome is observed carefully for the first 72 hours of life. Some infants may require hospitalization for as long as a week after birth.

Nicotine

Historically, nicotine inhaled via smoking has been termed a fetotoxic agent because of its relationship to low birth weight. Data now suggest that the delay in normal development associated with maternal smoking may begin during the embryonic period.[70] This phenomenon results from the effects of both carbon monoxide (leading to relative fetal hypoxia) and nicotine (leading to placental vasoconstriction). The effect on the fetus appears to be dose related and will cease if the woman stops smoking during pregnancy. Infants who are born to women who smoke are evaluated for gestational size and, if they are small for gestational age, treated accordingly.

Alcohol

Newborns born to women who abuse alcohol can suffer serious and permanent damage.[71,72] Ethanol readily crosses the placenta and the extent of fetal exposure to alcohol can be high. Damage is characterized as a continuum, with two terms being used to describe the damage: fetal alcohol syndrome (FAS) and fetal alcohol spectrum disorders (FASD). FASD encompasses FAS but also includes individuals with milder effects of alcohol.

Newborns exhibiting signs of FAS may have both physical and cognitive damage. Physical damage includes dysmorphic features that are congruent with a midline defect, which occurs early in fetal life. The manifestations of FASD are more subtle and will become obvious when

the child is older and has trouble with school or socialization. The signs of FAS may or may not be obvious during the newborn period. Damage varies with timing and dose of exposure. If physical or behavioral signs that are possibly indicative of FAS or FASD are noted, consultation with a pediatric team is necessary. These newborns need careful monitoring because of their risk for failure to thrive. Their behavioral characteristics may present a challenge for parents who are caring for them, rendering them vulnerable to abuse by caregivers.

Opioids and Other Illicit Drugs

Neonatal abstinence syndrome long has been associated with maternal use of opiates such as heroin and cocaine. More recently, neonatal withdrawal symptoms have been found among the children of women using various psychotropic drugs.[73-75] Maternal use of cocaine has been suspected as a cause of many fetal problems, most of them related to the intense vasoconstrictive properties of cocaine, which can cause placental and cord accidents. The known effects of cocaine exposure include behavioral problems that are secondary to central nervous system irritability. Cocaine-exposed newborns may be irritable, tremulous, and hard to comfort. They may favor a rigid, hyperextended posture. The manifestations of cocaine exposure are related to the amount, duration, and timing of fetal exposure. Third-trimester use is more likely to result in residual behavioral effects. Meconium is a particularly useful medium for drug testing because of the ease of specimen collection from the diaper and the ability to obtain accurate drug sampling of opiates and other prescriptive drugs that often are abused.[76] In some states and localities, a positive toxicology screen must be reported to child welfare officials.

Neonatal Abstinence Syndrome

In the case of opiates and potentially other drugs of abuse, the fetus becomes tolerant and can show evidence of severe withdrawal symptoms in utero if the mother stops using the drug during pregnancy. At birth, most newborns of women who are addicted to illicit drugs will exhibit some withdrawal symptoms.[73] These start in the first few days after birth and can persist for many weeks. If a woman used drugs by the intravenous route, her newborn will also be at risk of infection with the hepatitis and HIV viruses.

The symptoms of neonatal abstinence syndrome involve many neonatal systems, including central nervous system irritability, tremors, excess hunger and salivation, sweating, yawning, sneezing, fist sucking, and temperature regulation problems. Some infants progress to seizures and profuse vomiting and diarrhea. These newborns need to be managed by the pediatric team during an inpatient stay. Management considerations include providing a quiet, nonstimulating environment, a possibly increased need for calories and fluids, and potential need for pharmacotherapy to control symptoms. Traditionally methadone (Dolophine) has been the drug used to support withdrawal; however, buprenorphine (Buprenex) now is gaining popularity for this indication.

Newborns experiencing withdrawal need an environment that is not too stimulating. The

mother can be taught the swaddling and calming techniques. Healthcare providers have a particular obligation to help this mother identify resources that she can rely upon if she has difficulty coping with the newborn's behaviors.

Newborn Disorders

Several newborn conditions may adversely affect newborn health. One of the great challenges facing providers who care for newborns is the nonspecificity of signs and symptoms of some serious conditions. Because of the nonspecific nature, a careful history and physical examination to gather the maximum amount of data to report to pediatric caregivers is needed. The midwife practicing far from a pediatric inpatient facility should become familiar with techniques for starting a peripheral intravenous line in the neonate. If the neonate's condition deteriorates, it will be more difficult to find a vein.

Hyperbilirubinemia

As many as 50% of newborns develop clinically evident hyperbilirubinemia or jaundice.[77,78] Management of jaundice depends on whether the jaundice is determined to be physiologic or hyperbilirubinemia that is indicative of a pathophysiologic process. **Table 38-5** provides a list to help distinguish physiologic jaundice from hyperbilirubinemia.

Table 38-5 Newborn Hyperbilirubinemia

Type of Hyperbilirubinemia	Signs and Symptoms
Physiologic jaundice	Jaundice appears on days 2–4 after birth
	Total bilirubin rises slowly and peaks at day 3 or 4 of life < 13 mg/dL
Hyperbilirubinemia	Jaundice is visible during first 24 hours after birth
	Total bilirubin rises quickly, up to > 5 mg/dL /24 hours; it peaks at > 13 mg/dL
	Visible jaundice persists after one week of life
	Newborn may have risk factors such as cephalohematoma or ABO blood group or Rh (D) incompatibility, polycythemia
Breast milk failure jaundice	Jaundice appears in first week after birth
	Total bilirubin levels may rise to > 13 mg/dL
	Exclusively breastfed: feeds poorly, weight loss and signs of dehydration, infrequent urine output
	Delayed passage of meconium
Breast milk jaundice	Jaundice appears after first week of life and persists for up to 12 weeks
	Mildly elevated bilirubin levels that do not rise
	Feeds well, normal weight gain, normal urine output

Newborn physiologic jaundice is the result of bilirubin deposits in the dermis. Bilirubin levels rise during the first few days after birth, secondary to three aspects of newborn physiology:

- The newborn has more red blood cells than does an adult, and these red blood cells have a shorter lifespan. As fetal red blood cells break down so that fetal hemoglobin can be replaced with adult hemoglobin, heme catabolism produces bilirubin as a by-product.

- Bilirubin must be converted from an unconjugated (indirect) non-water-soluble form to a conjugated (direct) water-soluble form so that it can be excreted through urine and stool. The hepatic metabolism pathway that conjugates bilirubin is immature in the newborn and is not effective for a few weeks.
- Conjugated bilirubin must be broken down further by intestinal bacteria so that it can be excreted. Because the newborn has an essentially sterile gastrointestinal tract, conjugated bilirubin is reabsorbed and recirculated via the enterohepatic system more than it would be in an adult.

Thus, physiologic jaundice is the result of increased production of bilirubin at a time when elimination is delayed.

All newborns develop rising total bilirubin levels for the first few days after birth, and it is not uncommon for some bilirubin deposited in the skin to be evident as newborn jaundice. The mean peak of total bilirubin plasma levels occurs between 48 and 92 hours after birth and the average value is between 7 mg/dL and 9 mg/dL.

Some hospitals screen all newborns with serum total bilirubin levels at 1 day of age, and those infants with a level less than 5 mg/dL are not rescreened unless the clinical picture changes. Infant care practices that enhance clearance of bilirubin, such as early and frequent feedings to promote the passage of meconium, should be advocated. Delayed passage of meconium promotes reabsorption of bilirubin as part of the enterohepatic circulation. All parents should be educated about newborn jaundice and taught to assess the newborn in a well-lighted room or near a sunny window by blanching the skin to reveal the underlying color.

Hyperbilirubinemia in newborns who are equal to or more than 35 weeks' gestation at birth is defined as a total bilirubin level that is higher than the 95% on the hour-specific Bhutani nomogram. This nomogram is used in a standardized bilirubin calculator that accounts for gestational age at birth, risk factors, number of hours since birth, and bilirubin values. The bilirubin calculator is available on the Internet or as a medical app for smartphones or personal computers. The calculator determines the risk for hyperbilirubinemia and presents recommended management based on the degree of risk.

A total bilirubin level that is higher than 25 to 30 mg/dL is associated with a risk for bilirubin-induced neurologic dysfunction (BIND). This disorder occurs when bilirubin crosses the blood–brain barrier and binds to brain tissue. Unconjugated bilirubin is highly neurotoxic, and the term *acute bilirubin encephalopathy (ABE)* refers to cerebral symptoms associated with hyperbilirubinemia such as irritability, high-pitched cry, hypertonia or hypotonia, seizures, and possibly death if left untreated. The term *kernicterus* is used to describe the chronic and permanent sequelae of ABE in infants who sustain permanent cerebral damage as the result of hyperbilirubinemia. The incidence of kernicterus in full-term newborns is exceedingly rare, even in those who develop ABE. Because of the persistence of kernicterus, in 2004 the American Academy of Pediatrics recommended that all newborns be screened for elevated bilirubin prior to hospital discharge. Those with hyperbilirubinemia could have close follow-up planned. Screening for bilirubin concentration was added to the recommended elements of the newborn visit in 2017.[78]

Newborns at increased risk for hyperbilirubinemia include those who have a hemolytic

process, such as an ABO blood-type incompatibility, or accelerated red blood cells breakdown from a large cephalohematoma. Other risk factors include inherited red blood cell membrane defects, enzyme defects such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, newborn sepsis, and maternal diabetes.

Breast milk jaundice and breastfeeding failure jaundice are two additional forms of newborn jaundice. Infants diagnosed with *breast milk jaundice* have mild hyperbilirubinemia that persists beyond the first week of life and slowly declines between 3 and 12 weeks of life. These infants need to be monitored but rarely need treatment; continued breastfeeding should be encouraged. Although the etiology is not clearly known, it appears some women have a substance in their breast milk that stimulates reabsorption of bilirubin from the neonate's intestine. Conversely, *breastfeeding failure jaundice* occurs secondary to exclusive breastfeeding but inadequate intake. In this case, the infant loses weight and has slower bilirubin elimination and higher levels of reabsorption via enterohepatic circulation. Breastfeeding failure jaundice is not the result of breast milk per se; rather, it is the result of too little fluid and dehydration. This form of newborn jaundice appears in the first week of life and may need specific treatment for the jaundice in addition to interventions designed to establish lactation.

Bilirubin can be measured via a central venous sample or a point-of-care transcutaneous meter, or can be estimated via physical examination. Jaundice appears first in the face and has a cephalocaudal progression. Although bilirubin levels can be visually estimated based on the level of jaundice in the newborn, visual estimation is not sufficiently predictive to be relied upon for management decisions.

The treatment for newborn jaundice is phototherapy, and in severe cases exchange transfusion. The light from the phototherapy converts bilirubin to a water-soluble form that can be excreted. The American Academy of Pediatrics has issued guidelines for newborn jaundice that, although not all evidence based, are generally followed throughout the United States, especially regarding indications for phototherapy.[79] The following symptoms may indicate that the jaundice is not physiologic and the newborn needs a more extensive medical evaluation: vomiting, lethargy, poor feeding, weight loss, hepatosplenomegaly, apnea, temperature instability, tachypnea, dark urine or urine positive for bilirubin, light-colored stools, and jaundice that persists for more than 3 weeks.

Phototherapy is an effective treatment for newborn jaundice and can be performed at home. Home phototherapy is not as effective as the technology available in the hospital, however, and one recommendation is to initiate therapy at home only when a newborn has a serum total bilirubin level 2 to 3 mg/dL lower than when phototherapy is initiated in a hospital.[80] Home therapy is less expensive than hospitalization and allows mothers and neonates to stay together, especially for breastfeeding. Occasionally a woman is unable to manage the process at home. Outside the United States, a cholesterol-lowering agent, clofibrate, has been used in conjunction with phototherapy to reduce unconjugated bilirubin more rapidly, but additional studies are needed to assess its effectiveness.[79,80]

Respiratory Conditions

Respiratory signs are the most common abnormal finding in newborns. The most common pulmonary causes of neonatal respiratory distress in term infants are pneumothorax, aspiration of meconium, neonatal pneumonia, and transient tachypnea of the newborn (**Table 38-6**). Signs of respiratory distress include tachypnea (> 60 breaths/min), nasal flaring, retractions of intercostal muscles or sternum if severe, or grunting. Cyanosis, rales, or rhonchi are possible. Central cyanosis (of the trunk, lips, tongue, and oral mucous membranes) is a sign of serious compromise of the neonate's hemoglobin oxygen saturation and requires supplemental oxygen.

Table 38-6 **Common Neonatal Respiratory Conditions**

Associated Conditions	Comments
TTN due to longer period of time transitioning from fluid-filled to air-filled lungs	TTN lasts 48–72 hours with spontaneous resolution, although the newborn may need assistance with feedings and extra oxygen. Generally these infants are monitored in the hospital until TTN resolves.
Meconium aspiration that can result in pneumonitis, hypoxia, respiratory failure, and persistent pulmonary hypertension	Requires support from a respirator and occasionally ECMO
Neonatal pneumonia caused by bacteria, viruses, or other microorganisms	Anti-inflammatory agents and supportive therapy
Pneumothorax (unilateral or bilateral), often after mechanical ventilation and overdistension	A large pneumothorax is a pediatric emergency
Congenital anomalies causing airway obstruction or pulmonary obstruction	May require surgical intervention
Sepsis	Evaluate other signs of sepsis such as temperature variations

Abbreviations: ECMO, extracorporeal membrane oxygenation; TTN, transient tachypnea of newborn.

If the newborn is having respiratory distress, continued monitoring of heart rate and respiratory rate is necessary while awaiting pediatric consultation or transport. If possible, check the newborn's blood pressure. To assess the oxygen level, use a continuous pulse oximetry sensor attached to one of the neonate's fingers or toes. This method computes arterial oxygen saturation (SaO_2), with an acceptable level being between 92% and 95%.

Newborn Infection

The newborn may have a congenital infection or may become infected with a virus or bacterium during labor, birth, or the immediate postpartum period. The viruses most likely to cause congenital infection are toxoplasmosis, parvovirus, varicella, syphilis, rubella, cytomegalovirus (CMV), and herpes. Infants with such infections are often small for gestational age. They may present with signs that include early jaundice, hepatosplenomegaly, petechiae, and palpable lymph nodes. Some viruses cause cataracts, limb or cardiac defects, microcephaly, rash, or vesicles.[81] Thrombocytopenia may be evident on a complete blood count (CBC). The visible effects of infection will vary according to the timing of fetal exposure and the severity of the infection.

Management may include isolation of the newborn from other newborns and from pregnant

healthcare workers until the virus is identified. Usually the mother and infant can be isolated together. Cord blood is saved for further testing. Historically, TORCH testing has been a routine component of the assessment of infants who are small for gestational age. TORCH is an acronym for “toxoplasmosis, other, rubella, CMV, and herpes”; the “other” category includes tests for syphilis, varicella, and parvovirus as indicated.[82] Although the presence of immunoglobulin M (IgM) antibodies in the cord blood will help to confirm a suspected viral infection, it is rare that IgM antibodies are present to aid diagnosis. Often the diagnosis of congenital infection does not become clear until the infant is older. Treatment in the newborn period is symptomatic.

Infections caused by *Staphylococcus aureus* and *Staphylococcus epidermidis* are usually acquired after birth in hospital settings. Signs of neonatal sepsis include respiratory distress, vomiting, lethargy, apnea, and irritability. Common causes of bacterial infections acquired by newborns during labor are group B beta-hemolytic *Streptococcus* and *Escherichia coli*.

Cardiac Conditions

Cardiac problems in newborns result from a variety of causes and mimic a number of other problems, especially respiratory disease and sepsis. Pulse oximetry is advocated for all infants, as described earlier, and can be used to identify such problems. Some newborns will quickly demonstrate signs of an underlying congenital defect. These defects are usually structural in nature and may affect the heart valves, the walls between the atrium and the ventricles, or the heart muscle itself.

The primary signs of heart disease include central cyanosis, murmurs, and other cardiac sounds.[83] Depending on the defect, pulses may be either bounding or diminished. Pulses can vary in intensity from the upper to lower extremities. Similarly, based on the defect, a loud murmur may be present at birth or may not be heard until 1 to 2 weeks after birth. The cyanosis of heart disease may be present over the entire body, which differentiates this condition from the peripheral cyanosis often found among normal newborns. For infants with a ventral septal defect, oxygenated blood crosses over the opening in the septum and recirculates through the lungs. In this case, cyanosis often is not present and a murmur may not be heard until the infant reaches 2 or more weeks of age as the compensatory measure of increased pulmonary vascular resistance diminishes and more blood flows from left to right. This shift is characteristic of a large defect and may be associated with a subtle onset of congestive heart failure evidenced by tachypnea, feeding problems, and failure to thrive. A parent may describe troubling symptoms during a postpartum visit or during calls about breastfeeding. In smaller ventricular septal defects, the systolic murmur is heard soon after birth but will not lead to congestive heart failure.

Some newborns will not make the transition from intrauterine to extrauterine circulation. In these neonates, the pulmonary resistance remains so high that blood flow through the newborn lungs is decreased. This relatively rare phenomenon results in persistent pulmonary hypertension (formerly called persistent fetal circulation). Signs include tachypnea, nasal flaring, and intercostal retractions. Because of the high level of resistance from the lungs, the ductus arteriosus and the foramen ovale may stay open to provide right-to-left shunting. In this

case, peripheral pulses will be bounding, the precordium will be active, and a murmur will be heard.[84]

Midwifery management of newborns with acute signs of heart disease includes immediate consultation with the pediatric team and supportive care for the resulting respiratory distress. The newborn's heart rate and respiratory rate are constantly monitored. If heart disease is suspected, the blood arterial oxygen saturation of an upper extremity can be compared to that of a lower extremity. In persistent pulmonary hypertension, the saturation is lower in the descending aorta. Warm, humidified oxygen is provided via hood at high concentrations. When there is a cardiac problem, however, even high concentrations of oxygen may not yield normal results. If the newborn is tachypneic, oral feedings are withheld. The metabolic demands of respiratory distress will predispose the newborn to hypoglycemia.

Signs of Neurologic Disease

The most common sign of neurologic compromise in the newborn period is seizure activity. There are many causes of neonatal seizures, ranging from hypoglycemia to neonatal encephalopathy.[85] Treatment is based on the etiology of the seizure.[85] Prognosis is also related to the etiology more than the seizure activity itself, unless the seizures are prolonged or frequent.[85] In rare cases, a congenital abnormality in the brain may be present. In the older newborn, seizures can be an indicator of an inborn error of metabolism.[86]

Newborns may evidence various types of seizure activity. The most common is the subtle seizure. Signs of subtle seizures include sucking motions, chewing, bicycling of limbs, drooling, apnea, deviation of the eyes, and eyelid fluttering. These seizures are evidenced as short, repetitive bursts of activity. Such repetitive behavioral patterns can be observed during a newborn examination. Because there is an association between hypoglycemia and seizure activity, it is recommended to perform a point-of-care glucose screening when seizure is suspected. Because of the risk of apnea, the newborn with possible seizure activity is carefully monitored by professionals with expertise in this area.

Current treatment for a newborn with seizures secondary to hypoxia–ischemic encephalopathy includes therapeutic hypothermia or brain cooling.[85,87] Other types of seizures (multifocal, focal) are less common in newborns. The signs of these seizures include movement of one limb with progression to other limbs or movement of both limbs on one side of the body.

Nonvisible Congenital Defects

Tracheoesophageal fistula and esophageal atresia are not visible on physical examination. However, signs such as excess salivation, respiratory distress, swallowing problems, and abdominal distension will be present. If esophageal fistula is suspected, a sterile feeding tube can be introduced into the newborn's esophagus but will not be able to be passed more than 10 to 12 centimeters.[88] In such a case, the newborn is positioned in a prone position with the head elevated and oral feedings withheld. Aspiration of the esophageal contents by feeding tube attached to a syringe helps to minimize the chance of aspiration into the lungs.

Tracheoesophageal fistula and esophageal atresia often occur together.[89]

A variety of congenital defects can lead to intestinal obstruction in the newborn. Among these are malrotation and midgut volvulus, meconium plugs, meconium ileus, Hirschsprung's disease (megacolon), and imperforate anus. The major diagnostic signs of all these anomalies are bile-stained emesis and failure to pass stool. Significant abdominal distension will be present with meconium ileus, meconium plug, and Hirschsprung's disease.[90] Newborns with these signs must be evaluated immediately by a pediatric caregiver. No oral feedings should be given if bile-stained emesis is observed. If neglected, any of these defects can lead to intestinal perforation.

Discharging the Newborn from Early Newborn Care

In hospitals, a pediatrician is usually responsible for assessing newborn readiness for care by its parents at home; however, when the birth occurs in a birth center or a home setting, the midwife makes this decision. In any setting, the midwife should be confident that the parents understand the basics of newborn care and can feed the newborn comfortably. Many hospitals have specific criteria for discharge, such as passage of urine and stool, completed physical examination, or two successful feeds.[91,92]

When the newborn is discharged from the hospital early or is leaving a birth center, follow-up assessment is recommended for 48 hours later. Parents will need assistance with arranging age-appropriate testing such as metabolic screening after discharge. Transition between providers is facilitated if new parents know that the midwife remains available for questions.

The First Golden Month: Primary Care of the Newborn

The role of the midwife during the newborn's first month of life varies markedly. In some locales, the midwife has little formal role once the newborn leaves a birthing room. In other practices, the midwife will continue care of the mother and newborn throughout the first 4 to 6 weeks after birth. These midwives may work in a collegial relationship with pediatric providers, with the well-child care gradually shifting to pediatric or family healthcare providers.

Regardless of any formal expectation regarding the role of the midwife, the reality is that many parents will call the midwife with questions related to the care and well-being of their newborn. The midwife, conscious of the special connection between mother and child, promotes family well-being through involvement in care and provision of evidence-based advice.

Well-Neonate Surveillance: Physical Care of the Newborn

Parents have many concerns regarding the physical care of their newborn. Overall, they should be reassured that there is more than one right way to approach many physical aspects of their child's care. Many midwives help mothers learn about their infants by working with the mother–newborn dyad during a home visit (**Figure 38-2**). Various common conditions about which parents may have concerns are summarized in **Table 38-7**.

Table 38-7 Common Neonatal Conditions and Parental Concerns in the First Month of Life

Conditions/Questions	Comments	Treatments/Advice
Skin Conditions		
Diaper simple dermatitis	Flat, reddened areas Minimal skinfold involvement Neonate may demonstrate distress during cleaning/diaper	Gentle cleaning with water Frequent diaper changes Use of protectants (e.g., zinc oxide)

	changes	
Diaper dermatitis secondary to fungus	Usually due to *Candida albicans* Confluent erythematous lesions Often lesions remote from the main area (satellite lesions) Painful to the neonate, even when not touched	Topical antifungals (e.g., miconazole) Topical steroids (e.g., hydrocortisone)
Diaper dermatitis with secondary infection	Usually due to *Staphylococcus* or *Streptococcus* microorganisms Peeling skin Vesicles Exudates	Treatment based on type of microorganism involved
Cradle cap	Seborrheic exudates	Gently comb hair/scalp with oil (e.g., vegetable, olive) Remove exudate with shampoo Regular shampooing usually resolves issue
Erythema toxicum neonatorum and milia	Various eruptions, small vesicles or generalized rash	These dermatologic conditions are common in the first week of life and will spontaneously resolve. No treatment is necessary, and the condition does not appear to be painful to the newborn. Parents can be reassured that this is a normal transient finding in newborns.
Oral Conditions		
Thrush	Adherent white plaques on tongue, gums, and/or palate	Oral antifungals Also rule out mastitis if the mother is breastfeeding
Nasal discharge	Discharge may be apparent Occasional periods of irregular breathing Crusting around nares may or may not be present	Counsel parents to avoid bulb syringes; they can cause trauma and edema Saline drops Differentiate between nasal congestion and apnea (apnea is associated with low heart rate, pauses of 20 seconds or more)
Behavior		
“Fussiness”	Crying “Colicky” behavior Difficult to console Reasons unknown and likely to be unique to individual parent–newborn dyad	Multiple suggestions to console a baby— although no research that one method is better than another: Swaddling Talk with baby *en face* Cuddle, reposition, walk, or move with baby Attempt to feed or give pacifier Reduce environment sensory stimulation *Never shake a baby!*
Sleep		
Timing of sleep	Usually sleep 16–18 hours in first few days Variation more profound as baby grows, ranging from as few as 8 hours or as much as almost 20 hours by 4 weeks	Reassure parents that newborns do not necessarily have days and nights confused Most likely will take 12 weeks at least to start sleeping more during nighttime and may take 3–5 months based on melatonin and cortisol production

	Newborns are less governed by circadian rhythms than adults Sleep is associated with feeding; more likely to sleep during day	
Safe sleep	Newborns who sleep on their backs are less likely to experience sudden infant death syndrome (SIDS) Originally part of the national campaign “Back to Sleep”; now termed “Safe Sleep”	Newborns should be placed on their backs for sleep Should have “tummy time” or interactions when on abdomen only when the newborn is awake
Feeding[a]		
Adequate feeding	Newborn should feed multiple times daily (e.g., approximately every 2–4 hours) May lose 5–7% of birth weight in first few days of life	Proxy measures for adequate intake include: Weight gain at end of first week or beginning of the second week (usually 150–200 g per week) Stools and urine in diapers at least 1–3 times during each of the first few days of life Once lactation established, 3–4 stools and 5–6 wet diapers every day If difficult to ascertain if diaper is wet, place a soft tissue inside the absorbent diaper If no bowel movement or urine within 24–48 hours, consult pediatric provider
Car Safety		
Car seats	Newborns should travel in rear-facing car seats	Never leave a baby alone in a car Choose a car seat that meets U.S. safety standards (will be marked on box and tag). Because multiple car seats and models of cars exist, have the car seat installed by or verified by a car seat technician.

[a] More details can be found in the *Breastfeeding and the Mother–Newborn Dyad* chapter.

For example, an infant does not need a full bath daily. Newborns need to have their heads and diaper areas sponged whenever appropriate using a mild, nondeodorized soap, with the area then being completely dried. A full bath can be given occasionally when the parent has the time to make it a relaxing event for the newborn. Parents should be urged never to leave a newborn unattended in the bath. The soap, towels, shampoo, and clean clothes can all be organized before starting the bath. Slip-proof bath mats are inexpensive and helpful.

Parents may have preferences for which type of diaper to use—paper disposable or cloth—and the best type to use has not been determined. A few parents will choose to wash their child’s diapers themselves. If so, recommend that dirty diapers be presoaked using bleach and detergent and washed twice in very hot water without packing the washer too full, to ensure that bacteria are destroyed.

Family members may encourage new parents to dress infants in excessive layers of clothing. A general rule of thumb is to clothe the infant with as many layers as other persons in the room are wearing, plus one layer. Because infants cannot sweat effectively, symptoms of overheating are mainly a red skin color, irritability, and body warmth. Eventually the overheated infant will

appear lethargic. Infants also cool rapidly through inspired cold air. When taken outside on windy cold days, newborns should have a nonrestrictive covering near their faces.

From the earliest moments at home with a newborn, parents should evaluate the environment for safety risks. In the first months of life, these risks are primarily related to falling or becoming stuck in small places such as between the bars on the sides of cribs. Parents should also consider removing soft pillows, mobiles, and toys that may lead to suffocation from the site in which the newborn sleeps.

If parents choose to use a pacifier, the pacifier should be cleaned regularly and checked for signs of dirt or mold. Most pacifiers today have a design that promotes proper development of the muscles of the mouth. Pacifiers should never be placed on a cord around the baby's neck because of the risk of strangulation. Some newborns do not accept a pacifier, so parents devise other methods to help the newborn become calm (walking the baby, distracting the baby, encouraging thumb sucking).

When an infant sucks on a bottle for a prolonged period of time, the residual sugars from the milk or juice may contribute to childhood dental caries, also known as "baby bottle mouth." The accumulation of milk in the back of the oropharynx may lead to ear infections as well. Therefore, prolonged bottle feeding, especially by propping a bottle, should never be used to calm an infant.

Parents also need to recognize situations in which immediate pediatric care is needed for the newborn. **Table 38-8** lists some situations in which a pediatric provider should be consulted promptly.

Table 38-8 **Neonatal Signs and Symptoms Requiring Prompt Parental Reporting/Pediatric Referral**[a]

Danger Signs	Description
Temperature instability	Axillary temperature > 37.4°C (99.3°F) or < 36.5°C (97.5°F)
	Tachypnea (> 60 breaths/min) for > 60 seconds
	Pauses > 20 seconds (periodic apnea)
Abnormal respirations	Regular retractions, wheezing, grunting
Infection of umbilicus	Odor, drainage, or bleeding from umbilical stump
Infection of eyes	Purulent discharge from eyes
Jaundice	Icteric changes of eyes, chest, or extremities
Gastrointestinal signs	Projectile vomiting
Diarrhea	Bile-stained vomit
	No stools/no urination since birth
	Taut, swollen abdomen
	> 6 stools per 24 hours/bloody or very watery stools
General signs of illness	Cough
	Excessive number of stools or watery stools
	Poor muscle tone
	Sleepiness/refusal to feed/inability to rouse
	Poor suck
	Neurologic signs such as bulging fontanelle, irritability, abnormal reflexes

[a] This list is not comprehensive. Midwives who provide well-baby care develop relationships with local pediatric providers to learn preferred consultation routines.

Well-Neonate Care Visits

When a midwife is the provider for a newborn during the first 28 days of life, the neonate may be seen in an ambulatory setting, often at the same time the woman is seen for a postpartum examination. The purpose of this visit is fourfold: (1) to monitor normal growth and development, (2) to identify symptoms of disease, (3) to offer screening measures, and (4) to educate and support the parents. When a parent brings a newborn in for a well-child visit, every effort should be made to keep the infant from exposure to others, especially anyone who is ill. Whenever possible, the parents should be escorted into an examination room as soon as they arrive with their child.

The visit starts with a brief interview of the parent(s) or primary caregiver. Particular attention should be paid to unresolved problems related to the birth or the immediate care of the newborn following birth. The midwife should assess the well-being of the parents and look for signs of depression or inability to cope with the demands of the newborn. Inquiries should be made about help in the home, sibling reactions, and reaction of other relatives to the newborn. Particular emphasis should be paid to the infant's feeding patterns, levels of alertness, bowel and bladder patterns, and crying patterns.

A complete physical examination is performed. During the physical examination, the midwife has an opportunity to observe the parent–newborn relationship. Observing a feeding can provide valuable insight into the parental–newborn relationship and parenting knowledge.

The greatest part of the initial well-child visit should be spent soliciting parental concerns and offering guidance and anticipatory advice. Any midwife providing well-child care should have a clear relationship established for pediatric consultation or referral of any infant presenting with signs or symptoms of illness.

Conclusion

Although midwives are not commonly viewed as primary pediatric providers, they provide the first neonatal assessment as they give the newborn to its mother. Ongoing assessment during the third stage of labor gives the midwife an important role during the first Golden Hour. Even in areas where pediatric care quickly is assumed by other professionals, the relationship between a midwife and a woman and her family often means that as questions arise about the infant, the midwife may be the first person to be called. Through their acceptance of this responsibility, midwives have an integral role in caring for the health of society's future generations.
